INDUSTRIAL ADMINISTRATION AND ECONOMIC POLICY

FAR more effectively than the Limitation of Supplies Orders or the policy of concentration of production already announced by the President of the Board of Trade, the rationing of clothing in Great Britain has brought home to every member of the community the importance of utilizing to the maximum advantage all our resources of moneys, materials and man- or woman-power. The contribution and co-operation of the individual citizen are essential, but our war effort may fail of its full effect if they are not directed and utilized to the utmost by wise administration and skilful management, whether on the part of Departments of State or in industry. The significance of scientific management and sound administration can scarcely be overstressed. They affect most powerfully the morale of the general population, which in total war is of as much importance as maintaining morale in the fighting services.

There are, unfortunately, many signs that this is far from being generally realized, or at any rate invariably served, by management or administration, as recent reports of the Select Committee on National Expenditure indicate. Its recommendation that day-time manning strengths in the civil defence services should be reduced to the minimum consistent with safety was prompted largely by the importance of minimizing the detrimental effect on morale and efficiency of an unnecessarily large amount of standing-by and waiting. The severity of its censure on the Ministry of Health for failure to supply information which would permit a judgment as to whether nursing staffs in the emergency hospital service are excessive is to be attributed as much to the desire to avoid waste and damage to morale of staff kept standing by unnecessarily, while similar staff elsewhere is overstrained, as to the ineptitude and incompetent administration thus revealed.

Other disclosures of the detrimental effect of inefficient administration on economy are contained in the twelfth and fifteenth reports of the Committee. In the former, sharp comment is made on the deterrent effect, as regards suggestions for increased economy and efficiency, of the cumbrous machinery through which these suggestions have to pass before reaching a level at which decisive action can be taken. Sensible suggestions, moreover, have been turned down as a matter of routine, apparently before reaching an officer who was sufficiently informed to appreciate them. In the matter of complaints, this position leads to the

more vigorous or influential complainants taking undesirable short cuts to overcome their personal difficulties, and it does not appear that the administration has been sufficiently wise to appreciate the way in which this state of affairs merely increases the difficulties of others, engenders friction and reduces general efficiency.

Other indictments of administrative neglect of elementary principles of scientific management are seen in the fact that valuable information can often only be acquired by direct contact with those who have to give practical effect to decisions and are usually working away from headquarters, and the Committee comments that, however effective may be the various means of collecting information, this work will be wasted unless its results are rapidly brought to the notice of those who have power to decide what modifications of practice and policy may be immediately required.

The Select Committee points out that apart from the failure of information and criticism to percolate from those actually carrying out the work to those who are directing and controlling it at the centre, highly placed witnesses have made statements which suggest either that they are unaware of some of the relevant facts and considerations, or that they have not fully appreciated their practical significance. It is sometimes difficult to escape the impression that they work in an atmosphere which is too strongly buffered from outside impacts. Moreover, the Committee stresses the great importance that the facts which it has readily been able to collect, but which, under war conditions, it is unable to support by full publication of the evidence taken, should have been collected, sifted and studied by responsible officers in the departments. Only in this way can recommendations for reducing waste by increasing efficiency of management be judged in their correct setting.

Whereas the disclosures in the fifteenth report are primarily those of failures of human nature, the need for effective administration is no less clearly indicated. The suggestion that idle labour was becoming a permanent and undesirable feature in the aircraft industry generally is disturbing, and all the more in the evidence of management so inept that it failed to keep the essential records which the Select Committee has now recommended should be enforced. Similarly, the recommendations that the Ministry of Labour should endeavour by publicity to give women a better idea of the kind of factory work for which they are needed, that Sunday labour should be discontinued except for the maintenance and repair of plant and other essential purposes, and that the Ministry of Aircraft Production should do everything in its power to ensure that factories working for it, either commercially or on a management fee basis, observe district federation wage-rates and keep their bonus percentages in line with those of their neighbours, involve essentially reflections on the foresight, imagination and competence of the administrations concerned.

It would be unfair to suggest that the question of absenteeism, which the Select Committee finds so disturbing, is one for management alone. With so much evidence of inefficient, if not incompetent management, however, it is difficult to believe that improvement in this respect and the maintenance of a more scientific standard would not go far to reduce avoidable absenteeism to a figure when it should easily be possible to deal with recalcitrant elements in personnel. In any event, we cannot afford in war-time to tolerate ineptitude and incompetence in management. The Select Committee's reports alone afford sufficient evidence of the waste and difficulties which flow from this source.

Unquestionably these reports indicate that civil administration in Great Britain is far from attaining the standard that the country has a right to expect. The restrained criticism is a severer indictment of civil service efficiency than such violent attacks as those of Lord Percy, and it would be reassuring to learn what action has been taken upon recommendations so authoritatively prepared and objectively stated. Nor is the indictment of industrial management any less penetrating, and it is scarcely reassuring to find, in view of the shortcomings of industrial management simultaneously exposed, that leading positions in the Ministry of Supply, the Ministry of Aircraft Production, the Ministry of Food and the ministries concerned with economic reconstruction have been entrusted to representatives of industrial organizations, rather than to individuals on their outstanding ability.

It is for this reason that Mr. Hugh Quigley's pamphlet in "The Democratic Order" series* is timely. He subjects the whole structure and policy of industry in relation to efficient administration and control to analysis from the point of view of serving the needs of the community—the *raison d'être* of industry in the ultimate analysis. Funda-

* End Monopoly Exploitation: a Policy for Industry. By Hugh Quigley. (The Democratic Order, No. 15.) Pp. 63. (London: Kegan Paul and Co., Ltd., 1941.) 1s. net.

mentally he raises the question, not so much of industrial policy, as of the machinery of government and its adequacy under present and post-war conditions.

Mr. Quigley makes his first important point in suggesting that the present industrial order should be replaced by one in which industry is subordinate to the State, in so far as the State seeks to advance the public welfare, and in which industry does not at any point dominate the public, either through its organizations or through its methods of representation. This involves a sense of public responsibility as well as of efficient management which have not been approached even by the new types of public corporation. As Mr. Quigley points out, where such authorities as the British Broadcasting Corporation, the Central Electricity Board or the London Passenger Transport Board have failed, has been in their approach to the larger problems of public service which give the justification for their technical privileges. We can scarcely expect more of the executives of the industries bordering on coal-mining, building, iron and steel, chemicals, shipbuilding, electrical engineering, agricultural, or the distribution of foodstuffs, especially in the light of the evidence of the Select Committee on National Expenditure reports.

This judgment, however, narrows the problem to one not so much of executive ability or technical efficiency as to one of managerial responsibility and executive vision, and Mr. Quigley points out first that the character of new State enterprises such as the public utility companies tends to reflect the character of the national executive, and that accordingly some kind of division must be made between purely technical management, which is usually efficient, and the wider aspects of national policy which are expressed in such management. The nature and limitations of any organization created to obtain better results from the point of view of the public welfare are a matter for investigation and, for all his insistence on the necessity for some such development, Mr. Quigley is unconvinced that far-reaching nationalization is the remedy.

The great difficulty is that of higher control; this has never been adequately considered by those who advocate the most thorough-going socialization. Moreover, attempts to co-ordinate economic policy are faced with the absence of any conception of what the tactics of higher control in economic matters should be. This is the real reason for the confusion existing, for example, in agriculture and in the marketing and distribution of food.

If we accept as basic the principle that no public utility or industry should be allowed to have a vested interest other than that involved in efficient production, a considerable amount of well-defined and well-supported technical, economic and social research will be required before we can evolve the technique and policy for the higher impartial controlling authority, which must possess not merely advisory functions, but also full executive powers. It involves, indeed, reconsideration of the whole machinery of government. It will be recalled that the Haldane Committee, which clearly envisaged this problem, while firmly rejecting a proposal to concentrate the administration or supervision of private enterprise in production under the same department concerned with the administration of nationalized services, contemplated some development of the Board of Trade in this field of production, but laid its main stress on the need for further provision in the sphere of civil government for the continuous acquisition of knowledge and the prosecution of research to furnish a proper basis for policy.

Mr. Quigley takes no pessimistic view of the capacity of democratic government to evolve the appropriate instruments to prevent in future the development of industry without regard to the needs of the community. Protection against exploitation, increasingly high standards of public service on the part of industries and public utilities and the right to call to account, as those in military or naval command are called to account, those in charge of such industries and public utilities if their administration fails to display courage, vision or disinterested statesmanship—these are no Utopian ideals. Despite all the evidence of inefficiency or negligence or disregard of public interest, there is no sign that the community is unable to throw up, either in the service of the State or of industry, those possessing administrative ability, high ideals, wide vision and unassailable integrity. The fields of thought and inquiry opened up by Mr. Quigley and by the Select Committee's reports go far beyond the structure of industry and organization of government: they embrace the whole character of our educational system and its capacity to throw up leaders. That these suggestions should be voiced, however, attests the vitality of democracy and its capacity of adjustment and development to meet the changing needs of a dynamic society.

SCIENCE AND THE STRUCTURE OF SOCIETY

The Social Relations of Science
By J. G. Crowther. Pp. xxxii+665. (London: Macmillan and Co., Ltd., 1941.) 16s. net.

WHEN, eighty years ago, H. T. Buckle wrote his "History of Civilization in England", his main thesis was that the course of human progress could be traced in the growth of scientific truth. He applied scientific principles to the study of history, but measured progress too much by materialistic achievements for his analysis of causes to be accepted by historians as complete. Mr. J. G. Crowther takes a truer and broader view of the social and intellectual influences of natural knowledge, and is not so much concerned with maintaining a proposition as in presenting a picture of creative scientific thought and action. He has long been esteemed as a clear interpreter of scientific developments to general readers, through his articles in the newspaper press and other literary works; and he realizes fully the relations between these advances and the structure of society.

The theme of Mr. Crowther's book is essentially that of Francis Bacon's phrase: "All knowledge should be referred to use and action." This maxim is, however, not fully representative of Bacon's regard for the pursuit of knowledge as an end in itself, and the expression of a natural desire to discover the truth by experiment. His words, "Itaque ipsissimae res sunt (in hoc genere) veritas et utilitas", in Aphorism cxxiv of the "Novum Organum", have been variously rendered, but their meaning is "Truth and utility are in this kind the very things we seek for".

Whether or no Bacon held more liberal views of the relation between knowledge and practice than are expressed in the phrase which is the keynote of Mr. Crowther's book is, however, unimportant. It is contrary to the spirit of modern science to be bound by the words of any master; and the story of progressive knowledge and changing social conditions told impressively in the book implies nothing of this kind. It is a concise survey, under eighty-three headings, of the repercussions of science and society from the time when man became a tool-making animal to the present day. Man had to acquire knowledge of the properties of things around him in order to supply his daily needs. His primary purpose was "use and action", but this was often diverted into new directions by innate curiosity and the desire to control mysterious characteristics of natural objects and events. As a craftsman, he was concerned with applications of science and manual skill rather than with the philosophy of causes and consequences, which belonged to the fields of magic and religion.

Early man learned by practice how to increase food supply by the cultivation of plants and the domestication of animals, and by the invention of the bow for hunting and protection. He began to learn how to be master of Nature instead of her servant. The scope of interest and activity expanded from the family to the village and then to urban cities in the great river valleys of the Nile, Euphrates and Indus, with a consequent growth of specialization of function and increase of social authority. With this expansion were associated the concentration of wealth and distinctions of social status between craftsmen of various types and other members of the community. The introduction of organized warfare to extend possessions brought captives as well as land and booty. The captives became slaves; and the manual work involved in the crafts of metal-working, weaving, pottery and like creative activities lost its social dignity.

"The notable decline of invention", says Mr. Crowther, "after the stabilization of city life in Babylonia and Egypt occurs in parallel with the increase of slavery, the loss of status of craftsmen, and the concentration of wealth." He traces this decline through the classical period of Greece and Rome, when manual workers were of the slave class and most of the inventions were made by them. Concentration by the Romans upon law and administration led to the distinction "between the creative and organizing factors in civilization, which still persists, and is one of the causes of modern social disorder". Plato taught that pure science was a subject for gentlemen, and practical applications of knowledge were for people of a lower standard. He used the same Greek word in referring to the manual operations in surgery as in carpentry, with the result that the influence of his teaching led surgery to become the profession of barbers. Though Galen made his own dissections, his successors relegated them to slaves and servants because of the low esteem in which manual work of any kind was held.

It was a village carpenter, Jesus of Nazareth, who by his ethical teaching and noble life established a social philosophy in which the manual worker was again given his rightful place in society. "The Christian doctrine of human equality has had profound influence on the restitution of the dignity of human labour and this indirectly on

experimental science." It cannot be said that Christian civilization to-day, or at any time, has seen the fulfilment of the teaching of its Founder, but it represents a vast advance upon the conditions of life and service which prevailed in Græco-Roman times. Its defects are due not to faults in the humane principles of its message, but to the neglect to put them into practice. Lust for power and property, in individuals and in communities, is similarly responsible for the perversion of the gifts of science. Scientific workers are, however, beginning to realize that they have a social mission to undertake, as well as the right to pursue natural knowledge as an intellectual activity or with practical purpose in mind.

Mr. Crowther's suggestions as to the organization of scientific work on the basis of Bacon's maxim of "use and action" will not be readily accepted by those who believe in the pursuit of knowledge for its own sake, without regard for its proximate or ultimate service to the community, but the deplorable social and international conditions in the world to-day demand that heed should be given to them. His book is a thoughtful and thought-provoking sketch of the influence of science upon society and of society upon science. The apostle whom he follows is Bacon, whose insight into the social relations of science led to the foundation of the Royal Society. The early interests of the Society were in investigations planned to benefit mankind, but after a time they became specialized and professionalized, and the social contacts were correspondingly diminished. Mr. Crowther sees in the scientific movement in recent years, represented in addresses of presidents of the Royal Society and the British Association, and by the formation of the Association's Division for Social and International Relations of Science, signs of a revival of the Baconian principles of service. His interesting and stimulating book should help to dispose of the remark that "We learn from history, that we do not learn from history".

R. A. GREGORY.

BIOLOGICAL OXIDATIONS

Mechanisms of Biological Oxidations
By David E. Green. (Cambridge Biological Studies.) Pp. vi+182. (Cambridge: At the University Press, 1940.) 12*s*. 6*d*. net.

THE study of the mechanisms of biological oxidations has made such rapid strides during the last fifteen years that adequate reviews of the progress made are most welcome. Dr. Green's book gives a readable and concise account of many of the major advances which have been made recently in the field of biological oxidations.

The enzymes, important in oxidative systems, which Dr. Green describes are prefaced by a short introduction to the general properties of enzyme systems. The introduction resolves itself into a survey of the properties of amino-acid oxidase, an enzyme found in kidney extracts. This enzyme is chosen to familiarize the reader with the properties of oxidative enzymes, on the grounds that its general properties " may be assumed to parallel those of other oxidative enzymes". It is, however, unfortunate that Dr. Green should have chosen this example as a typical oxidative enzyme, for the amino-acid oxidase of tissue extracts is confined in its activities to the oxidation of the unnatural amino acids (that is, of the *d*-configuration). It must, therefore, be regarded as distinct from most other oxidative enzymes which attack naturally occurring substances. The enzyme has other properties not shared by most other oxidative enzymes; for example, it is able to attack a large number of substances having a special configuration, a property shared by hydrolytic enzymes and certain oxidative enzymes, but not shown by a large number of oxidative enzymes the most striking property of which is their specificity of attack; again it forms hydrogen peroxide as a result of its oxidative activity, a property shown by enzymes such as amine, choline and xanthine oxidases but not by the majority of dehydrogenases.

Possibly the property which Dr. Green is most anxious to demonstrate in the enzyme, the properties of which are assumed to parallel those of other oxidative enzymes, is the fact that the enzyme can be resolved reversibly into two constituents, a protein and a yellow compound neither of which is catalytically active but together form the active enzyme. The yellow compound, shown to be a flavin adenine nucleotide, has been termed a prosthetic group of the amino-acid oxidase. Many oxidative enzymes are now known to be capable of dissociation into a protein and a substance the chemical structure of which is known. Neither the protein nor the dissociated substance—the 'prosthetic group'—has catalytic properties; the combination of the two apparently constitutes the enzyme. This interesting fact,

made clear by the work of Warburg and of Euler, forms the main theme of Dr. Green's book.

Dr. Green considers that the oxidative enzymes are best classified by reference to the chemical nature of their prosthetic groups, and is evidently more concerned with such a classification than with any attempt to describe the enzymes with reference to their share—quantitatively as well as qualitatively—in the oxidative metabolism of the living cell.

The enzymes are named, following Warburg's nomenclature in describing enzymes, according to the chemical nature of the prosthetic group. They are grouped into the following classes :

1. *The iron porphyrin protein enzymes*—so called because the prosthetic group is iron porphyrin. These include catalase and peroxidase.

2. *The pyridine protein enzymes.* Here the prosthetic group is a compound of nicotinamide, ribose, phosphoric acid and adenine. The enzymes include a large number of the well-known dehydrogenases.

3. *The flavoprotein enzymes.* The prosthetic group is a compound of flavin, ribose and phosphoric acid. Adenine may also enter into the composition of the prosthetic group. These enzymes are responsible for the activation of *d*-amino acids, dihydrocozymase and probably of xanthine, hypoxanthine and certain aldehydes.

4. *Copper protein enzymes*—so called because copper appears to be indispensable for the activity of the enzymes and is united with the special proteins involved. Such enzymes are polyphenol and monophenol oxidases, laccase and ascorbic acid oxidase.

In all cases the highly specific structures of the enzymes are the proteins, one prosthetic group being capable of combining with a number of different proteins and forming different catalytic systems.

The adoption of the Warburg nomenclature is still clearly a matter for argument. It facilitates at present a certain clarity of exposition but its implications are such as not to be accepted by all workers in the subject.

Further chapters in Dr. Green's book deal with what are termed thiamino proteins, that is, enzymes such as carboxylase and pyruvic oxidase which require the presence of thiamine (or vitamin B_1) pyrophosphate for their activities, and with enzymes which Dr. Green finds difficulty in classifying but are grouped together as they all seem to reduce cytochrome in presence of their respective substrates without the necessity of an intermediate carrier. There is finally a block of enzymes which apparently defies attempts at classification and these are put by Dr. Green in a chapter entitled "Unclassified Oxidative Enzymes".

It is important to point out that this account of enzymic oxidations is limited largely to one aspect of oxidative phenomena, namely to those reactions taking place in tissue extracts or in isolated enzyme systems. The result of this limitation of treatment is that in a book consisting of 178 pages of text, 163 pages are devoted to descriptions of the properties, and the modes of preparation, of a variety of isolated oxidative enzyme systems, whilst the remaining pages are concerned with brief comments on oxidations as they are known to occur in intact animal tissues. Dr. Green remarks (p. 164) "there is a tendency for those who are engaged in the reconstruction of cellular oxidations to forget that the countless chemical permutations and combinations, of which the isolated components of oxidative systems are capable, cannot be assigned physiological significance until some counterpart of these events is shown to take place in the intact cell or organism. It is becoming increasingly clear that the study of enzyme systems cannot be divorced from the study of the intact cell and *vice versa.*" It is a pity, in view of such a commendable statement, that Dr. Green has not paid at least as much attention to the experimental facts bearing upon oxidations as they occur in intact cells and tissues as he has to the phenomena observed in isolated enzyme systems.

In a book of this nature, where most prominence is given to the enzymes the prosthetic groups of which have been the subject of much investigation, it is natural that there should be many omissions. It is, however, surprising that so little mention is made of the work on tyrosinase and melanin formation, that no reference is made to the mutual oxidations and reductions undergone by amino acids in presence of strictly anaerobic micro-organisms—reactions which are vital for the proliferation of these cells—that in a discussion devoted to glycolysis and fermentation no mention is made of the enzyme hexokinase, which transfers phosphate from adenylpyrophosphate to glucose or fructose and so on.

There are certain errors in the text requiring alteration. Thus on p. 25, line 22, "10 g." should read "50 g." and on page 113 there is a curve which may lead one to suppose that the copper content of polyphenol oxidase may reach 300 per cent!

Dr. Green's book must be considered of real value to the teacher and to the more advanced student of biochemistry, so long as the limitations which have been expressed above are recognized.

The book is well printed and produced. It is a pity, however, that its cover should be spoiled by some obvious misprints.

J. H. QUASTEL.

NORTH AMERICAN HARDY TREES AND SHRUBS

Manual of Cultivated Trees and Shrubs Hardy in North America

Exclusive of the Subtropical and Warmer Temperate Regions. By Prof. Alfred Rehder. Second edition, revised and enlarged. Pp. xxx+996. (New York: The Macmillan Company, 1940.) 42*s.* net.

THE first edition of this notable work appeared in 1927 and set a new standard for its kind. A nineteen-page supplement of corrections and emendations appeared in 1935. The original issue is now exhausted, and as in the interval new species and hybrids have been named and introduced and the cultivation of others extended, the new edition now includes more than 2,500 species fully described, with 2,685 varieties, and 1,940 species and hybrids briefly mentioned.

The small half-page map illustrating zones of hardiness in the United States has been replaced by one partly coloured facing the title-page. In the process of revision certain alterations have been made. Monocotyledons have been placed at the end instead of immediately preceding the Dicotyledons, and the bamboos subdivided into ten instead of three genera. Original authors are cited in parenthesis (for example, *Petrophytum cæspitosum* (Nutt.) Rydb.), a practice which may assist in tracing descriptions or illustrations. Varietal and other subdivisional epithets now immediately follow the specific name, the category proposed by the first author of a trinomial being placed immediately after it (for example, *Ribes alpestre giganteum* Jancz., var.). This is to avoid making numerous new combinations, since the author does not always agree with the conclusions of other botanists.

Sequoiadendron has been separated from Sequoia, Halimium from Helianthemum, and Weigela from Diervilla, all with good reason. There is a considerable increase (twenty-four species) in Rhododendron, reflecting the spread of this genus into American gardens. Some additions noticed are *Carmichælia australis*, the hybrid *Caryopteris clandonensis*, the monotypic genus Kalmiopsis, the bi-generic hybrids Gaulthettya and Pyracomeles, etc.

It is Prof. Rehder's intention, however, to publish a bibliographical supplement which will include not only exact citations of their source for all names and important synonyms mentioned in the "Manual", including both varieties and forms which are often difficult to trace, but also, in the case of trinomials, the category considered to be botanically correct.

In a work of this magnitude and detail typographical and other errors are almost unavoidable, although of the former many have been corrected since the earlier edition. Muhlenbeckia instead of Muehlenbeckia in the index, on p. 579 Parsonii for Parsonsii, and on p. 887 *Bambusa metake* for Metake are examples.

The spelling of certain specific names is apparently not always in accordance with the Rules. Instances are *Pyrus kumaonensis*, *Rhamnus Erythroxylon*, *Rosa Lheritierana* and *Spiræa Billiardii*.

A few authors are incorrectly cited, for example, *Prunus tangutica* Batal., for Koehne, *Lavandula latifolia* Vill., not Linn., and *Daphne hybrida* Sweet, not Lindl. Some recent changes in nomenclature have not been taken up, such as *Magnolia heptapeta* (Buc'hoz) Dandy, *Betula platyphylla* Sukatchev for *B. mandshurica* (Reg.) Nakai, and *Ulex minor* Roth for *U. nanus* Forst. The dates of introduction to cultivation are not always accurate; for example, *Forsythia Giraldiana* was introduced by Farrer in 1914, *Euonymus oresbius* and *Berberis sublevis* by Forrest about 1919, whilst Orphanidesia has been growing in England for some years, although only lately figured. The flowers of *Magnolia Dawsoniana* are now known and have been described. On p. 562 the derivation of Glossopetalon is supplied instead of *Forsellesia*, and *Rubus japonicus* Linn. is cited on p. 406 as a synonym of *Kerria japonica* (Linn.) DC., instead of the much more common *Corchorus japonicus* Thunb.

For the most part, however, these are comparatively small points which can be corrected as they are discovered. A more definite want, particularly to British users of the book, is the omission of a number of genera and species hardy in many parts of these islands and almost certainly equally hardy in Zone VII of Prof. Rehder's map. Azara, Desfontainea, Fabiana, Corokia and Mutisia come to mind, while *Cytisus Battandieri*, *Ceanothus rigidus*, *Telopea truncata* and *Viburnum Tinus* should certainly be included.

Apart from these criticisms it is scarcely possible to over-estimate the value of this comprehensive and laborious work to those whose work or hobby brings them into close contact with trees or shrubs. Nurserymen, botanists, foresters and amateur gardeners can all learn from it, and if it was more widely utilized there would be a great improvement in the general nomenclature of woody plants in cultivation. The new "Manual" is a most welcome addition to the bookshelf, and will become the same guide and authority which its predecessor has been.

B. O. Mulligan.

TSWETT'S ADSORPTION ANALYSIS

Principles and Practice of Chromatography
By Prof. L. Zechmeister and Dr. L. Cholnoky. Translated from the second and enlarged German edition by A. L. Bacharach and F. A. Robinson. Pp. xviii+362. (London: Chapman and Hall, Ltd., 1941). 25s. net.

THE removal of coloured impurities from solutions by shaking with charcoal is the most familiar application of adsorption, and chemists have shown enterprise in improving the adsorbent by 'activation' and in finding new ways of using the material. In applying adsorption to analytical problems, however, it was left to a botanist, Prof. M. Tswett, to display initiative and imagination and present chemists with a device of great value. He allowed coloured solutions to percolate through a compressed column of adsorbent, and by using finely divided calcium carbonate instead of charcoal, he was able to follow visually the track of the pigments. Different coloured substances travelled down the column at different speeds and the resulting separation into coloured zones could be enhanced by 'developing the chromatogram', that is, by allowing sufficient of the pure solvent to pass down the column after the solution had all come into contact with the adsorbent.

The possibilities of the new method were recognized very slowly. Tswett's monograph entitled "Chromophylls in the Plant and Animal Worlds" (Warsaw, 1910) was published in Russian, but the neglect of his work was not really due to inaccessibility because it was described in several papers in well-known German journals during the period 1906–12. Even the encomiums of Willstätter and Stoll in 1910 and 1912 made little impression, and it was not until 1931, when Kuhn and his colleagues succeeded in isolating pure α- and β-carotene by the use of the method, that Tswett's procedure came into its own. Nor can it be said that the potentialities of the method were unforeseen, for Tswett had himself predicted on good evidence, so early as 1910, that 'carotene' could be separated in this way.

The neglect which is often the fate of a new device or technique arises more often than not from what is practicable in research rather than from dullness of mind. Three advances contributed to the new interest in Tswett's work; the first was Pregl's in the technique of micro-analysis, the second the discovery that carotene was somehow connected with vitamin A, and the third was that the determination of the structure of carotene began to look feasible, Zechmeister having made a promising start. From 1931 onwards the successes of adsorption analysis have been so numerous that the method has become indispensable.

A monograph on the subject was produced a few years later and proved to be a model of its kind, and the need for an English translation was at once recognized by Mr. Bacharach in reviewing the first edition in NATURE (July 10, 1937). A second edition was soon called for (NATURE, April 8, 1939), and Mr. Bacharach has added to his many services to chemistry in producing this careful translation. If the English sometimes lacks the verve of the translators' own writings, it is meticulously accurate, apart from the title.

Chromatography, according to the dictionary, is the *description of colours*, and the word was used in 1731 and 1835 in the titles of treatises on colours and pigments. The title of Zechmeister and Cholnoky's volume, namely "The Chromatographic Adsorption Method", is perhaps a little cumbrous in English.

The book contains a full account of the many technical developments which have resulted from the wider application of the method and of the achievements to be credited to them. Each topic is dealt with in its proper setting, so that many fields of research are reviewed in an interesting way which adds greatly to the value of the work.

To carry out with one's hands a complete and flawless chromatographic separation is a difficult but satisfying achievement, and simple exercises can be devised which give students enjoyment and training in craftsmanship. Many perfectly developed chromatograms of leaf pigments were produced under the direction of Baly and Heilbron in 1922–23, and to-day the photographs recording those experiments tell their own story. A vast literature of research, however, lies in between, and it seems not unlikely that Tswett's method came into general use only when the time was ripe.

Zechmeister and Cholnoky in the preface to the second edition explain that they had intended to include a biography of Tswett, but they add that "trustworthy information about the active life of this pioneer has, however, not so far been available to us". It is to be hoped that circumstances will permit those who knew Tswett to provide a record of his life and work, for the debt we owe to him is great and increasing. R. A. MORTON.

Elementary Physics

For Medical, First Year University Science Students and General Use in Schools.

By Prof. G. Stead. Sixth edition. Pp. xiv+562. (London: J. and A. Churchill, Ltd., 1940.) 12*s*. 6*d*.

PROF. STEAD'S book is primarily intended for the use of medical students and first-year university students, though the author expresses the hope that it will be found useful for School Certificate and Higher School Certificate candidates. In a single book covering such a wide field, it is not possible to treat the various topics as fully as perhaps one would wish and it is intended that the book should be used in connexion with a course of lectures with practical demonstrations. So far as Higher School Certificate work is concerned, this plan would be necessary. In the main, the book is up to date; it seems a pity, however, that the more convincing method of using actual beams of light instead of pins in verifying laws in connexion with mirrors and lenses is not advocated. Also in a modern text-book surely less space should be devoted to the 'shadow' and 'grease spot' photometers, and more attention paid to modern instruments to bring the subject into line with modern practice.

The book is excellent in its way; the diagrams are good and plentiful, and so far as space will allow the facts are presented clearly. It is, however, definitely a book for specific examination purposes, and apart from the stress made on medical applications, there is little attempt to correlate physical principles with everyday life; probably for a single text-book too much has been attempted.

First Course in Theory of Numbers

By Prof. Harry N. Wright. Pp. vii +108. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 12*s*. net.

WHAT is the minimum knowledge of the theory of numbers that every mathematician should have? The question must be elaborated. "Should", because ignorance is likely to detract from his efficiency whatever his own field may be? Then he needs very little: the Euclidean algorithm and its direct consequence in the existence of identities of the form $ax-by=1$; nothing at all about continued fractions, if the current fashion is a safe guide. "Should", in order to discover whether the subject makes any appeal to him? Then add the elements of linear congruence, and a few classical theorems such as Fermat's. "Should", if he cares about being well-read in pure mathematics generally? Then include simple continued fractions and the law of quadratic reciprocity.

Prof. Wright's book is a college course, appropriate in scope to the last class of reader, and with a satisfying unity, but rather expensive regarded as a substitute for four or five chapters of a text-book on algebra. The author has succeeded in infusing his enjoyment of the subject into a sound exposition. Confusion on the eastern side of the Atlantic is almost inevitable: this bookwright is not Prof. Hardy's collaborator in the same domain. E. H. N.

Calculations of Quantitative Analysis

By Prof. Carl J. Engelder. Pp. viii+174. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 12*s*. net.

THIS book, which is up to the English Intermediate Degree standard, gives a straightforward account of the theory underlying the calculations in quantitative analysis. The text is illustrated by a large number of worked-out problems, and each of the fifteen chapters concludes with original calculations for the student to work out for himself. Answers are only given to the odd-numbered problems, since these are intended for home-work, but those to the even-numbered problems can be obtained on application to the publisher.

The book is divided into four parts. The first part is devoted to general considerations such as the use of logarithms and the methods of designating the strength of solutions. The calculations in volumetric work are considered in the second part, and this includes the calculation of values in acid-base titrations. Part 3 is devoted to gravimetric analysis and includes a chapter on the solubility product principle. The fourth part deals briefly with the application of analytical data, as for example, the calculation of atomic weights.

The subject-matter in these four parts is generally sound and up to date, though the statement (p. 58) that salts of the sodium chloride type are ionized 80 per cent or more in 0·1 *N* solutions is not in keeping with modern theory. Similarly, it is confusing to find a calculation (p. 129) on the hydrogen ion concentration of a mixture of 0·5 *M* acetic acid and 0·3 *M* sodium acetate in which an allowance is made for the 78 per cent ionization of the salt.

At the end of the book, in addition to an index and logarithm tables, there is a large number of tables of physical properties, such as the specific gravities of acids and alkalis and the solubility of salts, which should prove very useful in the laboratory. A. C. C.

Organic Chemistry

By Dr. F. Sherwood Taylor. Third edition. Pp. xi+588. (London: William Heinemann, Ltd., 1940.) 10*s*. 6*d*.

DR. TAYLOR has established a reputation as a writer both of text-books and more popular works on science, and he is thus able to put a little more feeling into his descriptive organic chemistry than is customary—some of the compounds seem to have life and uses and to be something more than colourless crystalline compounds having the formulæ indicated. It is a task to get all organic chemistry into 500 pages; the same number of specialized monographs would scarcely do it. Yet something has to be provided to enable the student to beat the examiner. The book has a biological bias as is to-day proper: it contains the essential significant facts about the commoner organic compounds, the presentation is clear and we have no hesitation in recommending it as in many ways superior to its competitors.

E. F. A.

THE ORIGIN OF MAN

By Dr. R. Broom, F.R.S.
Transvaal Museum, Pretoria

WHEN, in 1924, Dart of Johannesburg discovered a type of fossil anthropoid more man-like than the chimpanzee or gorilla, a new chapter was opened in the early history of man. Dart named his fossil form *Australopithecus africanus*, and he regarded it as somewhat intermediate between the living anthropoids and man, and probably near to the anthropoid from which man arose. The first account of the discovery was given in NATURE of February 7, 1925.

The skull which Dart had discovered was unfortunately that of a young child-ape of about five years, and a few of the rather striking human resemblances were no doubt due to the immaturity of the specimen; and the majority of men of science were not inclined to accept Dart's opinion. They regarded the animal as closely allied to the chimpanzee, though with a few human characteristics apparently acquired by a parallel development. One authority considered that the skull is only "the distorted skull of a chimpanzee".

A few of us have consistently maintained since 1925 that Australopithecus is not only not a chimpanzee, but also that it is not at all closely allied to the chimpanzee, and that it has many characters that prove it to be near to the human ancestor.

In 1929 Dart removed the lower jaw from the upper and revealed for the first time the occlusal surfaces of the crowns of the milk molars. The side view of these teeth had shown that they were markedly different from those of the chimpanzee and gorilla, and were very like those of man. The occlusal surfaces now fully confirmed this view. They showed that Australopithecus cannot be nearly allied to any of the living anthropoids.

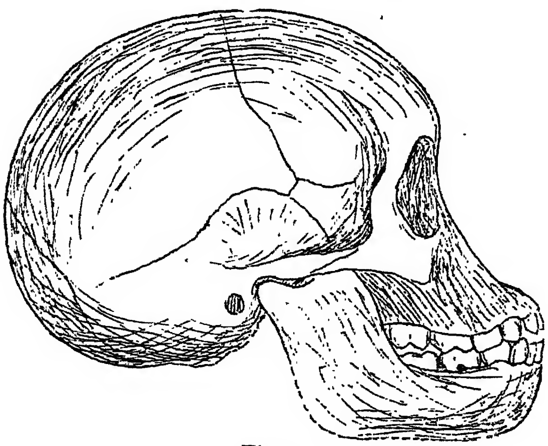

Fig. 1.
SIDE VIEW OF SKULL OF *Australopithecus africanus* DART. ½ NATURAL SIZE.

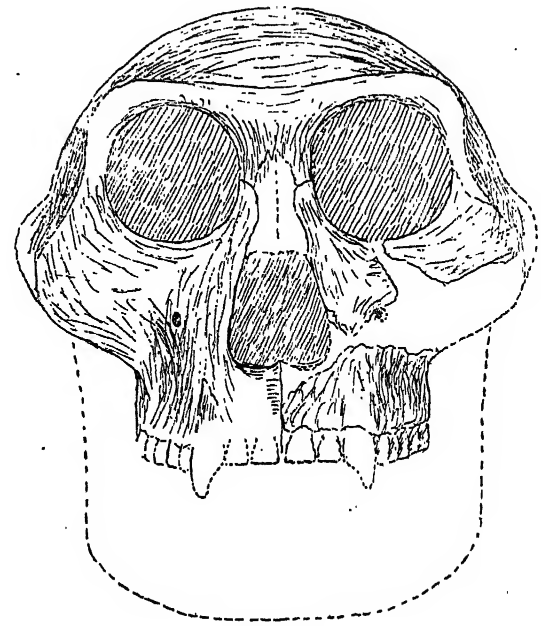

Fig. 2.
FRONT VIEW OF FACE OF *Plesianthropus transvaalensis* (BROOM). ½ NATURAL SIZE. THE PARTS SHADED ARE KNOWN IN THE TYPE. THE MANDIBLE IS UNKNOWN IN THE TYPE, BUT CONSIDERABLE PORTIONS ARE KNOWN IN OTHER SPECIMENS.

The first upper milk molars in the gorilla and chimpanzee have two main cusps. In man there are three; and Australopithecus agrees with man. The first lower milk molar in the gorilla is a flattened tooth with one large pointed median cusp and indications of small anterior and posterior cusps. In fact, it is not unlike the premolars of the dog. In man the first lower milk molar is entirely different. It is a molariform tooth with four well-marked cusps. In Australopithecus the tooth agrees closely with that of man. In the chimpanzee the tooth is like that of the gorilla with some rudiments of the ancestral condition. By no possibility can man have been derived from an anthropoid with degenerate and specialized teeth like those of the gorilla or chimpanzee. The four cusps which we find in man and Australopithecus are manifestly the four cusps found in the milk molars of the cercopithecids, such as the baboon. Man must have come from an anthropoid which still retained the cercopithecid type of

milk molars; and must have had a remote cercopithecid ancestor.

We need not here discuss the brain of Australopithecus. Dart and Elliot Smith considered that it showed some strikingly human characters; others thought the case not proved. Dart even went so far as to maintain that the structure of the brain showed that it was a bipedal animal, like man.

As Dart's type was only the skull of a young child-ape, the world remained unconvinced, and wanted an adult skull. So in 1936 I set about looking for one, and in a few weeks was successful; and not only got one, but parts of three others with many isolated teeth. Then in 1938 I got a good skull of what I consider to be a third new genus of man-like ape.

For many months I have been working at the Sterkfontein type skull, and have now completed a reconstruction of it; and it seems but right to reveal at the earliest possible moment how this anthropoid looked. I shall not here discuss at length my reasons for regarding this Sterkfontein ape as belonging to a distinct genus from Australopithecus. Manifestly the two forms belong to very different geological ages. The Sterkfontein, which I call the *Plesianthropus transvaalensis*, is probably of Middle Pleistocene age. The Taungs ape is almost certainly very much older. Probably it belongs to the Lower Pleistocene, but just possibly it may be Upper Pliocene.

Plesianthropus, as will be seen from the illustrations, has a skull somewhat like that of the chimpanzee in size, but differing greatly in many characters. Though the skull is that of a male, the canine, though fairly large, is unlike that of the chimpanzee, and there is practically no diastema between it and the second incisor. The cheeks are broad and more like those of the gorilla and orang than those of the chimpanzee. The nasal bones are only partly known, but from the upper parts of the maxillæ we can be confident that the nose must have been more man-like than ape-like.

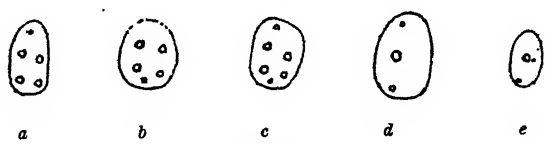

Fig. 3.

DIAGRAMS OF THE CUSPS IN THE FIRST LEFT LOWER MILK MOLARS IN VARIOUS PRIMATES. *a*, BABOON; *b*, AUSTRALOPITHECUS; *c*, BUSHMAN CHILD; *d*, GORILLA; *e*, CHIMPANZEE (ALL NATURAL SIZE).

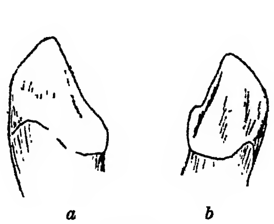

Fig. 4.

INNER SIDES OF LOWER CANINES OF ANTHROPOIDS (NATURAL SIZE). *a*, CANINE FROM YUNNAN, REGARDED BY WEIDENREICH AS CANINE OF AN ORANG, BUT BY THE WRITER AS MORE PROBABLY AUSTRALOPITHECINE CANINE AND POSSIBLY THE CANINE OF GIGANTOPITHECUS (FROM CAST); *b*, CANINE OF MALE *Plesianthropus transvaalensis*.

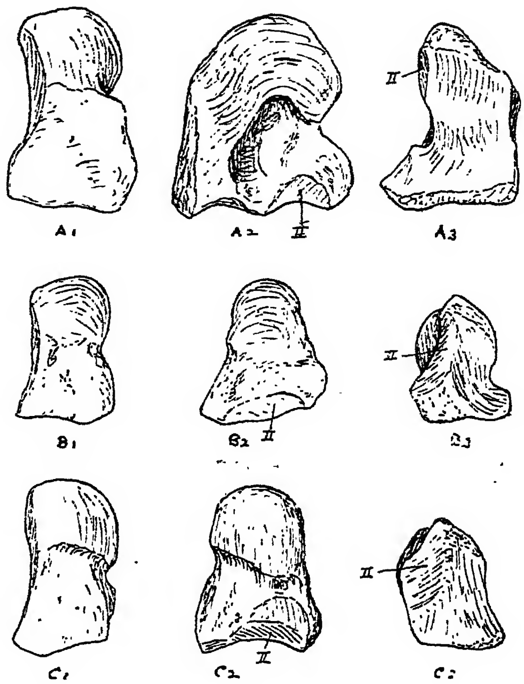

Fig. 5.

THE OS CAPITATUM (OR OS MAGNUM) OF THE CHIMPANZEE *A*1, *A*2 AND *A*3; OF THE STERKFONTEIN APE *B*1, *B*2 AND *B*3; AND OF THE BUSHMAN *C*1, *C*2 AND *C*3. DORSAL, RADIAL AND DISTAL SIDES. THE ARTICULAR SURFACES INDICATED BY II ARE THOSE FOR THE IIND METACARPALS.

The teeth, though a little larger than those of man, are almost typically human, and not very like those of either the chimpanzee or gorilla (Figs. 3 and 4).

The most interesting tooth in Plesianthropus is the lower canine. It is of a type almost unique. It differs markedly from the lower canines of the living anthropoids, and there are no known fossil canines at all like it, except one. On the posterior border of the tooth there is a very distinct small cusp with, in front of it on the outer side, a moderately deep vertical groove, and on the inner side in front of it a very deep groove. This little cusp is a typical cercopithecid character lost in all known anthropoids, except one. Weidenreich figures a lower canine from a cave at Yunnan which he refers to a "fossil orang". In my opinion this is unlikely to be the canine of an orang.

Von Königswald has described some teeth of a

large anthropoid under the name *Gigantopithecus blacki*. These were found in Chinese drug stores, and are believed to have come from somewhere in southern China (possibly Yunnan). One of these teeth, a second upper molar, so closely resembles the molars of the Kromdraai skull, Paranthropus, though very much larger, as to suggest that Gigantopithecus will prove to be an Australopithecine. Possibly Weidenreich's supposed fossil orang tooth came from the same locality, and will prove to be the lower canine of Gigantopithecus. In any event it is a tooth essentially similar in structure to the lower canine of Plesianthropus, and thus most probably an Australopithecine canine. Occasionally in man we find distinct evidence of this cercopithecid cusp, but usually it is lost in man as in the living anthropoids.

As I have recently shown, Plesianthropus has a maxillary antrum, which is fairly similar to that of man, and not at all like that of the chimpanzee.

The lower end of a femur which we may regard as practically certainly that of Plesianthropus closely resembles the femur of the Bushman, and is not like that of any of the living anthropoids. The only known wrist bone is very similar to that of a Bushwoman and differs greatly from that of the chimpanzee. I recently gave a figure of this os magnum or os capitatum, and for comparison the corresponding bones in some other Primates. Unfortunately, the supposed chimpanzee bone figured is really that of the orang. I therefore give a few other figures to avoid any possible confusion. Curiously enough the chimpanzee bone is less like that of Plesianthropus than is that of the orang, and it is distinctly more baboon-like, though it has no os centrale (see Fig. 5).

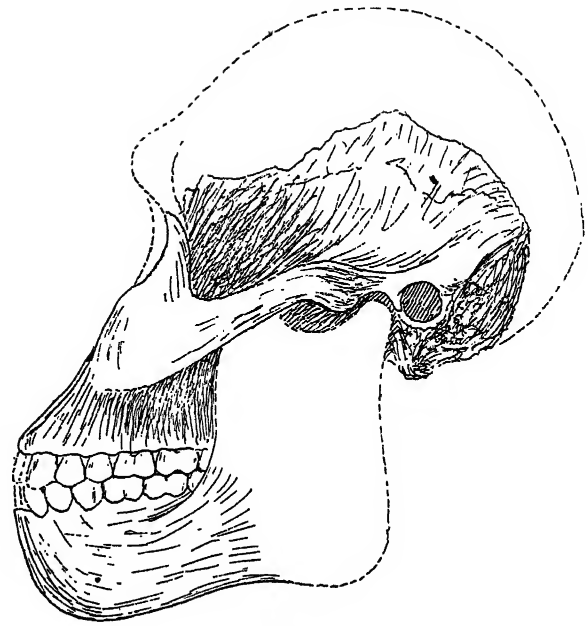

Fig. 7.
SIDE VIEW OF THE KROMDRAAI SKULL, *Paranthropus robustus* (BROOM). APPROX. 3/7 NATURAL SIZE. THE SKULL IS PROBABLY THAT OF A MALE.

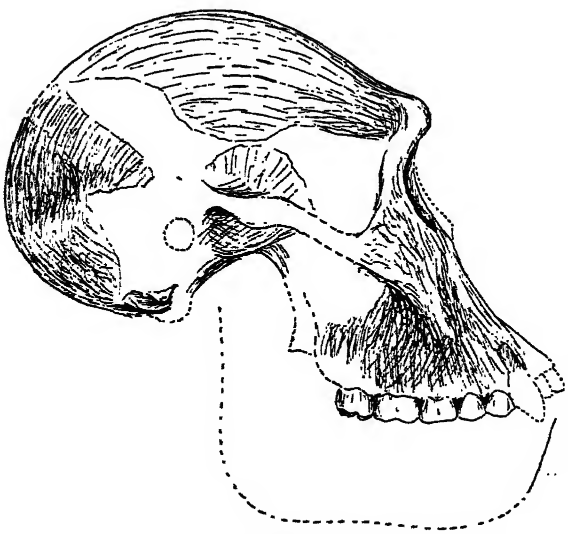

Fig. 6.
SIDE VIEW OF SKULL OF *Plesianthropus transvaalensis* (BROOM). APPROX. 3/7 NAT. SIZE. THE PARTS SHADED ARE ALL KNOWN IN THE TYPE SPECIMEN. TWO OF THE TEETH ARE DRAWN FROM THOSE OF THE LEFT SIDE. THE SKULL IS THAT OF A MALE.

In neither the orang, the gorilla nor the chimpanzee is the os capitatum like that in man. One very important difference is that in man the distal end of the bone gives a large articulation to the second metacarpal. In the chimpanzee and gorilla the distal end gives no articulation to the second metacarpal in the specimens I have examined, but there is a small articulation for it on the radial side. In the orang there is a similar radial articulation and a small distal articulation. In Plesianthropus the condition is essentially as in man, with a large articulation on the distal end for the second metacarpal. Probably the large articulation for the second metacarpal in man is due to the greater development of the metacarpal in connexion with the well-developed thumb. In the orang the thumb is better developed than in the gorilla and chimpanzee, and here there is a small distal articulation on the os capitatum for the second metacarpal. We are perhaps justified in concluding from the structure of the os capitatum in Plesianthropus that it, like man, had a useful opposable thumb.

The Kromdraai ape, *Paranthropus robustus*, is a third type of South African Australopithecid. It differs in many characters from Plesianthropus. It has a smaller canine and a very differently shaped face, and the premolars are much larger and differently shaped. It is also of a different geological age. The baboons associated with it

are of different species from those at Sterkfontein, and so are the species of Procavia. Though probably of Middle Pleistocene age, it may be many thousands of years older than Plesianthropus.

The skull gives us the perfect glenoid cavity which is almost typically human in structure, and quite unlike that of either the chimpanzee or the gorilla. The brain is probably considerably larger than that of Plesianthropus. Though only some fragments of the mandible of Plesianthropus are known, we have a good lower jaw of Paranthropus. Its teeth are almost typically human, but the premolars are very large ; while the canines are remarkably small.

We have the distal end of the humerus and the proximal end of the ulna of Paranthropus. These were found with the type skull, and there cannot be the slightest doubt that they belong to the same individual. They are almost typically human in structure, and very unlike those of the living anthropoids.

The South African caves have shown us that there lived in Pleistocene times various anthropoids which in many characters were much nearer to man than the living anthropoids. They had larger brains, and almost the human type of teeth, and there is considerable reason to believe they were mainly bipedal. They certainly were not arboreal, and they probably hunted in packs. There is reason to believe that they used sticks or stones for digging and as weapons. We can scarcely doubt that, though not yet human, they were nearly related to man.

Man was undoubtedly on the earth in Upper Pliocene times and must thus have been living in Europe and Asia when the known Australopithecines were inhabiting South Africa. Though it is thus improbable that any of the known South African Australopithecines can have been the ancestors of man, the discovery of these very man-like anthropoids shows us that there once lived a group of anthropoids so near to man in structure that we seem forced to believe that man has come from a Pliocene Australopithecine.

Though the gorilla is well removed from man's ancestor, he must be more nearly related to man than is the chimpanzee. Man and Australopithecus have retained a number of cercopithecid characters lost in the living anthropoids, but manifestly the gorilla and chimpanzee must have had cercopithecid ancestors. The cercopithecids have very marked ischial callosities. These are retained in the gibbons, and are occasionally well marked in the chimpanzee, but are lost in the orang, the gorilla and man.

Some years ago I argued that man must have sprung from a heavily built anthropoid such as the gorilla, which had to use its hallux for support, otherwise he would have lost his great toe, as has the kangaroo to-day. If I am right in assuming that Gigantopithecus was probably an Australopithecid we have perhaps in this giant form an anthropoid very near to that from which man arose.

The structure of the teeth in man and the Australopithecines seems to prove conclusively that man and the anthropoids must have come through a cercopithecid line as they have cercopithecid characters not found in the lemurs or the tarsioids. The living anthropoids have lost many of the cercopithecid tooth characters, but the orang retains sufficient to leave no doubt of the cercopithecid ancestry.

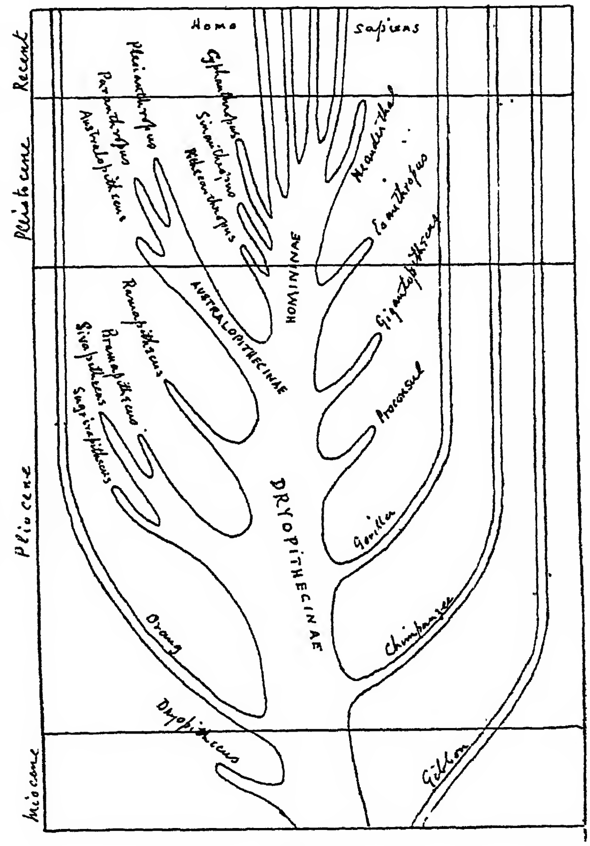

Fig. 8.

Phylogenetic relationships of man and the higher anthropoids.

I think there can be no reasonable doubt that man arose in Middle or more probably Upper Pliocene times from a large Australopithecine ape. The known Australopithecines are near relatives of this ancestor. The living anthropoids are much more remote relatives.

Though there are many who object to genealogical trees—and certainly some of those that have been published have been unsatisfactory—some-one must be correct ; and the one I here give may

with further knowledge have to be modified, but I think it cannot be very far from the truth.

In the tree I give, attention may be directed to the placing of Ramapithecus nearer to the base of the human stem than the other Siwalik types, and to the placing of Proconsul higher up than is usually done. Hopwood regards Proconsul as a Lower Miocene form "related to *Dryopithecus* and ancestral to the chimpanzee". I have only seen the cast, but incline to place it nearer to the gorilla, and appreciably higher. Possibly the supposed Miocene age is wrong.

The reasons for the various conclusions to which I have come will be given at length in the long paper I have in hand on the South African Pleistocene Anthropoids.

A NEW PROCESS FOR LIQUEFYING AIR

BY J. H. AWBERY

IN nearly all refrigeration processes, whether for the moderate cooling associated with food preservation or for the liquefaction of the 'permanent' gases, the operations are basically similar. A gas or vapour is compressed, the heat due to this compression is removed, and the fluid then allowed to expand, whereby it cools below the temperature of its surroundings. In the Linde process for making liquid air, the compression is to about 200 atmospheres, and the expansion takes place through a nozzle, the resulting cooling being that due to the Joule-Thomson effect ; the process is made cumulative by using the cold air to lower the temperature of the air which is still approaching the nozzle. Now the Joule-Thomson effect is by no means large in gases so nearly perfect as air, and it has long been realized that much greater cooling could be obtained in the expansion if this could be carried out in such a way that the gas did work, so that more energy would be removed from it. Mechanical difficulties, such as that of lubrication and of avoiding excessive heating due to friction, have caused designers to favour the theoretically less efficient expansion valve, though Claude had successfully applied the principle as early as 1906.

In an article in *Voks Bulletin* (November–December, 1940), Prof. P. Kapitza gives a brief description of an installation which has now been set up at the Institute of Physical Problems of the Academy of Sciences of the U.S.S.R., in which the expanding air does work by driving a turbine. The increased temperature-fall, as compared with free expansion through a nozzle, is so great that the initial compression need only be of the order of 5 atmospheres, instead of the 200 atmospheres necessary in Linde's process.

The main difficulty to be overcome was the design of the turbine itself, which is quite inefficient if the axial-flow impulse turbine used with steam is taken as a model. Owing to the low temperature, the air flowing through the turbine has a density five times that of steam at 250° C., so that there is a considerable centrifugal force as the fluid whirls around, and this must be taken into account, just as it is in a water turbine.

The present apparatus, which will be followed by larger ones, has a piston compressor working at 400 r.p.m., taking 50–80 kw. of electrical energy and delivering nearly 600 kgm. of air per hour at about 7 atmospheres. The compressed air then passes a water cooler and through the regenerator (cooled by previously treated air) to the turbine. The latter works at 40,000 r.p.m. and yields 4 kwh. of mechanical energy. The pressure drop is 4 to 1, and the cooling is such that air entering at – 158° C. emerges at – 187° C. (the boiling point of oxygen), implying the extraction of 3,700 calories per hour. The efficiency is thus 0·79–0·83. The regenerators also offer some novel features. There are two of them, used intermittently for about 26 sec. each, the change-over being effected automatically. They are filled with flat ribbon, 0·1 mm. thick and 50 mm. wide, with nodules.

From the turbine, the main air-stream is passed through the inner tubes of a condenser, only a small by-passed stream flowing through the outer tubes and being liquefied therein. The overall efficiency of the apparatus is such that it gives 29–30 kgm. of liquid air per hour, at an energy cost of 1·7 kwh. per kgm. It is calculated that this can be reduced to 1·2 kwh. per kgm. by making use of the mechanical energy from the turbine and by more suitable valves and other equipment, so as to utilize the full seven atmospheres compression, instead of only four-sevenths of it. If so, the apparatus will have about the same efficiency as present high-pressure installations.

It is even hoped that by working on a much larger scale, where heat losses are relatively smaller, the efficiency may rise to 1·1 or even 1·0 kwh. per kgm. of liquid air. In any event, as a laboratory installation, the outfit has many advantages, noteworthy among them being the short starting period (20 minutes or less) and the small dimensions, due to absence of decarbonizers, scrubbers, desiccators and other auxiliary gear.

THE SEARCH FOR ECONOMIC PLANTS*

By SIR ARTHUR W. HILL, K.C.M.G., F.R.S.
DIRECTOR, ROYAL BOTANIC GARDENS, KEW

THE search for plants yielding spices and the history of their cultivation and use, as well as the story of the transport of the spices, is a romance which includes accounts of geographical discovery, monopolies, economic warfare, annexations of territories, and all the vices of theft, envy, hatred and malice, and all uncharitableness enumerated by the Apostle St. Paul.

Perhaps the spice which should be put in the forefront is pepper (*Piper nigrum*), native of Malabar and of the forests of Travancore, a spice now too seldom seen or appreciated in its natural condition as black pepper corns, which was the staple article of trade between Europe and India for many ages. Most people to-day use white pepper, which is the small berry-like fruit or peppercorn, ground after its pericarp has been removed, thus depriving it of some of its pungency and best seasoning qualities.

Pepper was well known to Theophrastus in the fourth century, B.C., and to Dioscorides and Pliny, the former stating it to be a product of India. Its export from Baraké on the Malabar coast, near Calicut, is recorded in A.D. 64, and black pepper is one of the spices on which the Romans levied duty at Alexandria about A.D. 176. The first particulars we have, that it was a climbing plant "sticking close to high trees like a vine", occur in the writings of Cosmas Indicopleustes, a merchant and later a monk, who wrote about A.D. 540.

The wealth of Venice and Genoa largely depended on this spice, for tribute was levied in pepper, when money was scarce; it was often enacted that rents should be paid partly in pepper, and the Easterlings, according to the Statutes of Ethelred (A.D. 978–1016), coming in their ships to Billingsgate, had to pay at Christmas and Easter for the privilege of trading with London, a small tribute of cloth, five pairs of gloves, ten pounds of pepper and two barrels of vinegar. Now the only survival of this practice is the 'peppercorn rent', which signifies a merely nominal payment. The merchants who trafficked in spices in England were known as pepperers, and existed as a guild in the reign of Henry II and later were incorporated in the Grocers' Company.

Pepper, gums, myrrh, frankincense and cardamoms reached Europe mainly either by the Persian Gulf through Mesopotamia and Syria to the Levant or by the Red Sea and the Gulf of Suez and thence overland to Alexandria, while some consignments were conveyed by Arabian or Chinese traders to a port in southern Arabia and thence overland by the Frankincense route via Petra to Gaza and to Acre. From Alexandria or from the Levantine ports to which the spices had come overland they were shipped in the days of the Roman Empire to Rome, and later to Venice or Genoa, which cities for so many years held the monopoly of the traffic in spices.

During the Middle Ages the price of pepper was exorbitant. The high cost of pepper was one of the main inducements to the Portuguese to search for a sea passage to India, in order to break down the Venetian monopoly in this and other spices. Vasco da Gama anchored off Calicut in May 1498, and thus to pepper very largely, therefore, may be attributed the discovery of the Cape of Good Hope.

About the year 1500 the cultivation of pepper was taken up in the western islands of the Malayan Archipelago, especially in the islands of Rhio and Penang, and in Johore. The Dutch East Indies, Singapore, Penang, Ceylon, India and Indo-China are now the chief sources of supply.

The Venetians made every effort to retain the valuable traffic in their own hands, but in 1522, the first consignment of pepper reached Antwerp direct from India in a Portuguese ship, and the trade continued to be a monopoly of the Crown of Portugal until the eighteenth century. With the development of the all-sea route the overland traffic gradually came to an end. With regard to India, the century of Portuguese conquest of the west coast may be recalled, then their ousting by the Dutch, and finally, British dominion under the East India Company, and the efforts of the French and Danes to secure a share in the lucrative trade. Pepper thus was one of the principal economic products which has not only greatly enriched those who have held monopolies in its traffic, but has also incited geographical discovery, resulting in wars to secure possession of its native country.

Cloves, cinnamon, cassia, nutmegs and mace each have a history in which high enterprise, warfare, subterfuge and theft have all played their part.

Cloves are the dried flower buds of *Eugenia caryophyllata*, which is said to be native only in the five small islands of the Moluccas proper

* The substance of a lecture delivered before the Royal Geographical Society.

(Ternate, Tidore, Mutir, Machian and Bachina). The tree was introduced to Amboyna before the arrival of the Portuguese and is still cultivated there and in some of the neighbouring islands. Cloves are probably one of the oldest known of the spices, for it was customary for the Chinese Court officers, under the Han Dynasty, 266 B.C., to hold cloves in their mouth before addressing the Sovereign, to give their breath an agreeable odour. Nicolo Conti, a Venetian merchant, 1424–48, discovered the source of origin, previous writers having assumed that the places whence the spice was shipped, Ceylon, Java, or Malacca, were the homes of the plant. To the Portuguese however we owe our first accurate localization and description of the clove-tree, furnished by Pigafetta, the companion of Magellan, as he saw it in 1521.

For nearly a century the Portuguese were in control of the Spice Islands and had the principal share in the clove trade, until 1605, when the Dutch took possession of the Moluccas, and attempted to control the trade. They tried to restrict the tree to the Amboyna Islands—as they did with the nutmeg—and destroyed trees that might be growing elsewhere. Supplies however managed to reach England independently, though the Dutch monopoly was nearly complete until the latter end of the eighteenth century. Intrigue and theft apparently have played a very important part in the history of the clove in more recent times, for in 1770, the Governor of Mauritius and Bourbon, M. Poivre, procured living plants, both of cloves and nutmegs, and established them in those islands. The clove industry of Zanzibar and Pemba is due to an Arab from Zanzibar, who managed to obtain plants in Mauritius and took them about the end of the eighteenth century to his own island. Great Britain also took her share in what were probably illicit introductions of the spice plants, for, after Penang was founded in 1786 by Captain Light, the East India Company deputed Christopher Smith—one of the Kew collectors sent out by Sir Joseph Banks and George III—to visit the Moluccas and bring back spice plants (cloves and nutmegs) for cultivation.

The cultivation of cloves is now being extensively developed in Madagascar, which may prove a menace to the industry of Zanzibar and Pemba.

One of the present-day problems of economic plants relates to cloves, since the trees in Zanzibar are affected by a die-back disease, which demands careful research into ways of combating the malady and possibly of finding forms or varieties that may be resistant.

Nutmegs, *Myristica moschata*, are natives of the eastern islands of the Moluccas (Ceram, Banda) and of New Guinea. Nutmegs and mace, the crimson network arillus surrounding the nut, were imported into India at an early date by the Arabians and thus reached the West.

The home of the nutmeg was mentioned by Masudi about A.D. 918, and by the middle of the twelfth century nutmegs and mace were being imported to Aden, and duty on them was being levied at Acre about A.D. 1180. Ten years later they, with other aromatic products, were used in fumigating the streets of Rome at the coronation of the Emperor Henry VI. By the end of the twelfth century, nutmegs and mace were well known in Europe, but very costly, for about 1284, 1 lb. of mace cost 4*s*. 7*d*., the value then of three sheep or half as much as a cow. The Portuguese discovered the plant in Banda in 1572 and held the trade until they were driven out by the Dutch. The Dutch tried to restrict the trees to Banda and Amboyna by destroying the trees in all the other islands. In this however they appear to have been frustrated by pigeons, which swallowed the seeds and deposited them in neighbouring islands.

Great Britain occupied the Spice Islands during 1796–1802, and thanks to Christopher Smith's mission and the activities of Sir Stamford Raffles, nutmegs and cloves were introduced to Bencollen (Sumatra) and Penang. Plants were sent to Kew about that time and thence to St. Vincent and Grenada, where nutmegs now flourish.

Cinnamon (*Cinnamomum zeylanicum*), native of Ceylon, and cassia bark, the product of *Cinnamomum cassia* from southern China, are probably the earliest known of the spices. Frequent references occur to them in the Bible, and Theophrastus, Herodotus, Dioscorides, and other ancient writers refer to them as precious odoriferous substances. Cassia is mentioned in the earliest Chinese herbal, about the year 2700 B.C. To the Chinese may almost certainly be attributed the discovery of cinnamon in Ceylon, since they traded to Ceylon in very early times, and were no doubt familiar with the Chinese cassia-yielding species of Cinnamomum, which is very similar in appearance to the true cinnamon of Ceylon. An Arab writer, Kazwini, mentions cinnamon as a product of Ceylon in 1275, as do Ibn Batuta, the Muhammadan traveller, 1340, and Nicolo Conti, a hundred years later. The Portuguese discovered Ceylon after circumnavigating the Cape, and occupied the island on account of the cinnamon. Then the Dutch captured Ceylon, again because of cinnamon, about 1656, and established a monopoly in the spice, burning, as they did nutmegs, the stocks in Holland when the supply was greater than the demand. The English took Ceylon from the Dutch in 1796, and the East India Company held the monopoly in cinnamon until 1833.

(*To be continued.*)

OBITUARIES

Prof. F. Aveling

PROF. FRANCIS AVELING, professor of psychology in King's College, London, died on March 6, aged sixty-five.

The distinctive place in the development of British psychology which the late Prof. Aveling held, resulted from the rigorous training in philosophy to which he submitted himself before taking up his main work. Many others of his generation had reached psychology by the same route, but few have so succeeded in bringing their earlier discipline to bear fruitfully upon an empirical science. His study of the scholastic writers had given him a passion for precision and definiteness of thought, but never tempted him to forsake the experimental path for the *a priori*. His views were always as clear and hard in outline as one would expect from a student of St. Thomas, yet he was ready to modify them at any time when new evidence was presented.

Aveling was generous to a fault in his appreciation of the work of others. He could not believe that honest and persistent scientific effort could fail to reach at least partial truth, and in his later years some of his most interesting work lay in an attempt to evaluate the work of schools whose tenets were apparently opposed to those he held, believing it possible to show that their theories were not so much antagonistic as complementary to his own. He ascribed to controversial opponents his own obstinate integrity of mind, and was convinced that they could not have missed the mark completely. In the same spirit he always tried to relate his researches to those of others, believing that progress depended more on co-operation than on claims to originality. At the end of his life his views and sympathies (never narrow) were so broadening that one fears that his finest work remains undone.

His philosophical interests were probably responsible for the direction taken by his most important researches. His fine work on the "Consciousness of the Universal" was directed to the old problem of how the mind can achieve general thought, when all its process, as dated events, must be particular. This he approached in the light of the researches of the Würzburg school. After the interruption due to the War of 1914–18, in which he saw service, his work in this field was resumed by his pupils, who probably carried the study of the phenomenology of thinking as far as it is likely to go. From this he passed to volition, and an important series of studies were carried out in his laboratory. Here, too, his philosophical training is evident in his resolute facing of difficult theoretical problems, when he was driven to distinguish sharply conation from the decisive direction of effort exercised by the self. This work was summarized in "Personality and Will".

A little earlier he had published the "Psychological Approach to Reality," in which he applied the noegenetic principles of Spearman to the refutation of solipsism. But though his love of philosophy may have determined his own contributions to psychology it did not limit his activities. Only those who knew his laboratory well can properly appreciate Aveling's work. An enormous range of research was carried on there by his pupils, extending from elaborate experimental studies of perception to social psychology, each piece of work being designed to link on to other work in progress there or elsewhere. Much ingenious apparatus was designed and made in those cramped, inconvenient rooms. He popularized the tachogram method of experimentation on the psycho-galvanic reflex.

But the most lasting memory, and the truest, is of Aveling among his enthusiastic pupils, upon whom he bestowed so much affection, and so large a measure of his energy.

A. W. WOLTERS.

Mrs. H. H. Brindley

THE sudden and untimely death on April 3 of Mrs. H. H. Brindley has deprived us not only of an able entomologist but also of one of the most accomplished field ornithologists of her generation.

Maud Doria Haviland was a great-granddaughter of the famous Dr. John Haviland, professor of anatomy and then regius professor of physic at Cambridge from 1814 until 1851. She spent a large part of her early life in south-eastern Ireland, and it was here as a schoolgirl that the love of birds and wild animals developed. Although her outlook at first was that of the sportsman and field naturalist (she was a keen rider to hounds and a good shot), she was soon teaching herself vertebrate anatomy from text-books and taking every opportunity to practise dissection. Scientific publication began in 1913 with papers on ornithological subjects. In 1914 she went to Siberia as naturalist to a small anthropological expedition from Oxford, and this resulted in a delightful traveller-naturalist book "A Summer on the Yenesei" (1915). The war years 1914–18 were crowded with varied activities: residence at Cambridge, where she mastered the more technical aspects of biology with remarkable facility; driving a motor lorry over the rude tracks of the Bessarabian steppe, where she acted as chauffeur to a contingent of the Scottish Women's Hospital; and ambulance driving in the Paris-Soissons region for the French Red Cross. This period culminated in her election to a research fellowship at Newnham College in 1919, held until her marriage in 1922 to Mr. H. H. Brindley, fellow of St. John's College,

That Mrs. Brindley was a first-class field ornithologist her numerous papers show clearly. But she was also an entomologist of real ability. She published several valuable papers on the bionomics and post-embryonic development of various minute chalcid and cynipid hyperparasites of aphids, and she also produced excellent systematic work on the Mem-

bracidæ (Hemiptera) on which group she was an acknowledged authority.

In 1922 she visited the rain forests of the Essequibo and Demarara Rivers in British Guiana, and this expedition was the climax of her career as a field naturalist. During all her travels her outlook had been that of the ecologist, and the experience of tropical conditions enabled her in 1924 to give a memorable course of lectures to the Tripos class in zoology on certain aspects of animal ecology. This course resulted in a book entitled "Forest, Steppe and Tundra: Studies in Animal Environment" (1926), which is of permanent value as a series of essays linking the then somewhat youthful science of animal ecology with the outlook of the field naturalist. In this book there is much which deserves frequent re-reading, passages full of sound sense and keen insight. Her vivid and individual style expresses much of the woman herself—the energetic personality with its intense joy in the beauty of living things, combined in such a rare way with a critical appreciation of the scientific problems of the interaction of animals with their environment. But how can one describe adequately the charm of her company, the kind-hearted sincerity of her friendship and the irresistible delight and gaiety of her conversation? She possessed a most whimsical humour, kindly yet penetrating, and her skill as a *raconteur* was incomparable. The sincere sympathy of a wide and varied circle of friends will go out to her husband and daughter. Her passing leaves a gap which cannot be filled.

W. H. THORPE.

Prof. H. Freundlich, For.Mem.R.S.

SUPPLEMENTING the notices referring to Prof. H. Freundlich, which appeared in NATURE of May 10, Prof. J. Traube writes:

I have been termed the founder of scientific *Kapillar-Chemie* (see, among other papers, Freundlich, "I. Traube, zum 70sten Geburtstag", *Kolloid-Zeitschrift*, **50**, 194; 1930). My papers are so nearly related to those of Freundlich, that I feel it a duty to write some words in memory of the man who has done such excellent work on colloid chemistry and especially on *Kapillar-Chemie*.

In view of Prof. Rideal's article, I must restrict myself to the special connexion between Freundlich's work and my own. Freundlich created the name "Traube's Rule". He directed special attention to this rule, and he was the first to recognize its importance.

More interesting is, perhaps, Freundlich's agreement with me with regard to the theory of solutions. I have at all times declared, in contradiction to van 't Hoff and Arrhenius, W. Ostwald and W. Nernst, that the well-known theory of van 't Hoff and Arrhenius is only partially right, that not the number of particles and ions only are to be considered, but especially the effect of the particles with regard to the surface tension, etc., and that the theory of solution is not so similar to the theory of gases as van 't Hoff supposed. I was very glad when I read in Freundlich's article written in honour of my seventieth birthday that Freundlich wrote, "es heisst nicht mehr 'entweder oder' sondern 'sowohl als auch'"; and when the editor of the journal, Wolfgang Ostwald, in deference to the memory of his father had suggested that certain changes in the article should be made, Freundlich replied, "In this case the changes would be made still more in favour of Professor Traube".

From a letter dated February 14, 1940, which Herbert Freundlich wrote to me from the United States, I was very glad to learn that he also had accepted my conception of the existence of different particles of liquids and gases above and below the critical temperature, which displaces the Andrews and van der Waals' theory of continuity. He recalled also that Prof. O. Mass in Montreal had acknowledged these ideas.

Prof. J. W. C. Gunn

THE death of Prof. John William Cormack Gunn at the age of fifty-two will prove a severe loss to the University of Cape Town, for he had occupied the chair of pharmacology since 1919, had done much to establish the medical school and in recent years had served as dean of the Faculty of Medicine.

An Orcadian by birth, Gunn took his medical degree at Edinburgh. He obtained several academic prizes, and after qualification devoted himself to teaching and research in pharmacology. He acted as assistant first at Edinburgh and then at University College, London. He served in the R.A.M.C. throughout the War of 1914–18 and on demobilization became lecturer at the Queen's University of Belfast. He left this post to take the chair at Cape Town in 1919. At Cape Town he carried out researches on the pharmacology of South African native plants and inspired research among many of his graduates.

As time went on, Gunn's energies were more and more absorbed in the administrative work connected with the rapidly growing School of Medicine. He showed a special aptitude for this work and was warden of the Medical Students' Residence, curator of the Wernher-Beit Medical Laboratories and dean of the Faculty of Medicine. Gunn's cheerful personality made him popular both as a teacher and as a colleague and his loss will be felt severely by a wide circle of friends both in South Africa and in Great Britain.

We offer our sympathy to his wife and two sons.

A. J. CLARK.

WE regret to announce the following deaths:

Sir David Wilson Barker, president during 1903–5 of the Royal Meteorological Society, on June 15, aged eighty-two.

Mr. C. W. Jeffries, director of the Royal Observatory, Hong-Kong, since 1932, on June 22.

Prof. Robert Robison, F.R.S., professor of biochemistry in the University of London and head of the Department of Biochemistry at the Lister Institute, on June 18, aged fifty-seven.

NEWS AND VIEWS

Prof. R. W. Wood, For. Mem. R.S.: Henry Draper Medallist

The Henry Draper Medal of the National Academy of Sciences awarded to Prof. R. W. Wood, of Johns Hopkins University, at the 1940 annual meeting of the Academy, in recognition of his contributions to astronomical physics, was presented to him during the annual meeting in April last. Prof. Wood's contributions in the field of physics have been many and varied, and in the field of astrophysics three important researches, among many others, stand out especially. The first is Wood's pioneer work on resonance radiation and its applications to solar and stellar spectroscopy. A second is his development and skilful use of absorption screens of many types for astronomical and spectroscopic photography. Finally, and perhaps more important of all for the future of astrophysics, are the remarkable advances he has made in the construction of diffraction gratings. The use of the grating to produce a spectrum has been limited hitherto almost wholly to the sun and to bright sources in the physical laboratory ; by selection and shaping of the point of his ruling diamond, Wood succeeded in throwing as much as one half of the incident light into a chosen order of the spectrum. In addition, he was the first to achieve excellent results in ruling gratings on films of aluminium evaporated on glass. As a result, a modern Wood grating with high concentration of light is one of the most effective instruments of research in stellar spectroscopy. It has made possible the analysis of the spectra of the brighter stars on a large scale, has opened up the almost unexplored ultra-violet region of stellar spectra, and has already led to discoveries of interest regarding the constitution of the gases in interstellar space.

Sir C. V. Raman, F.R.S.: Franklin Medallist

Dissemination of news in war-time is difficult and this somewhat belated intimation of the award of the Franklin Medal to Sir Venkata Raman is a result of the slowed-down process. It is good news, however, to hear that Raman has obtained this high honour "in recognition of his many brilliant contributions to physical science and of his leadership in the renaissance of scientific work and scientific education that has occurred in India during the last thirty years". Raman joins the very distinguished company of Franklin medallists, which includes Rutherford, Thomson, Marconi, Bragg, Planck, Arrhenius and T. W. Richards. Not only has Raman personally made important contributions to theoretical and experimental physical science, but he has also lit the torch of scientific research for a large number of his countrymen who are turning out much distinguished work.

Sir C. V. Raman has worked on many branches of physics—optics, acoustics, and more particularly on the light scattering, which, in his honour, is now almost universally referred to as Raman effect. His discovery of this effect in 1928 not only inspired its exploration by himself and his students, but also started physicists and physical chemists in every country of the world to investigate it. Through its investigation far-reaching conclusions regarding the structure of molecules can be adduced ; its utility and importance need not be stressed here, but are reflected in the large number of papers which have been, and continue to be, published on the subject. Raman has received many honours from learned societies and institutions and, in addition, a knighthood in 1929 and the Nobel Prize in physics in 1930. In congratulating Raman on his latest honour, we hope that he will continue for many years to exert his powerful influence in conducting and directing, with sustained distinction and success, the fundamental problems of physics in which he has so indelibly established his reputation.

Louis E. Levy Medal of the Franklin Institute

The Committee on Science and the Arts of the Franklin Institute has announced that the Louis E. Levy Medal will this year be presented jointly to Profs. John M. Lessels and Charles W. MacGregor, both of whom are associate professors in the Department of Mechanical Engineering, Massachusetts Institute of Technology, for their paper entitled "Combined Stress Experiments on a Nickel-Chrome Molybdenum Steel". The Levy Medal is awarded annually "to the author of a paper of especial merit, published in the Journal of The Franklin Institute, preference being given to one describing the author's experimental and theoretical researches in a subject of fundamental importance".

John Moyes Lessels was born in Dunfermline, Scotland, on February 5, 1888. He was educated at Herriot Watt College and the University of Glasgow. During 1920–31, he was manager of the mechanical division of the research laboratories of the Westinghouse Electric and Manufacturing Company at East Pittsburg, and afterwards he was engineering manager of the South Philadelphia works. Since 1936 he has been associate professor of mechanical engineering at the Massachusetts Institute of Technology. He is technical editor of the *Journal of Applied Mechanics*.

Charles Winters MacGregor was born in Dayton, Ohio, on May 25, 1908. He attended the Universities of Michigan and Pittsburg, and during 1929–34 he was a research engineer with the Westinghouse Electric and Manufacturing Company at East Pittsburg. In 1934 he went to the Massachusetts Institute of Technology as instructor in mechanical engineering, and was appointed assistant professor in 1937.

Invalids and 'Fortified' Flour

THE Medical Research Council has issued a statement dealing with a suggestion that invalids may be harmfully affected by the consumption of bread 'fortified' with calcium. The need for this supplement is brought about in two main ways: first, the wartime diet in Great Britain tends to be deficient in available calcium, especially since restrictions have been imposed upon the sale of milk and eggs; secondly, the high content of cereal foods in the diet increases the amount of calcium it is necessary to ingest, partly because most cereals are deficient in calcium but also because the phytic acid in cereals often prevents the body from making use of the calcium they contain. The Ministry of Food has asked the Food Rationing (Special Diets) Advisory Committee whether the addition of small supplements of calcium salts to flour would be in any way deleterious to invalids. In reply, the Food Rationing (Special Diets) Advisory Committee has expressed the opinion that "there is neither medical nor scientific evidence that the consumption of bread made from flour fortified by the addition of appropriate quantities of calcium salts is harmful to patients suffering from any type of disease". This opinion was based on the following considerations.

It has been proposed by the Accessory Food Factors Committee of the Lister Institute and of the Medical Research Council that 14 oz. of calcium carbonate be added to each 280 lb. of 85 per cent extracted flour and 7 oz. of calcium carbonate to each 280 lb. of white flour. Expressing these quantities in other terms, it can be said that 1 lb. of the 'fortified' 85 per cent extracted flour and 2 lb. of the 'fortified' white flour contain slightly less calcium that 1 pint of fresh milk. There can therefore be no objection to the use of this fortified flour on the grounds that it will result in the consumption by invalids of harmful amounts of calcium. It has been suggested, however, that it might have a deleterious effect upon certain invalids because the calcium added to it is in a form—calcium carbonate—different from that which exists naturally in food. This criticism appears to be ill-founded. There is direct evidence obtained on human beings that the calcium of calcium carbonate is as available to the body as that of calcium phosphate. In an easily assimilable food, such as milk, calcium is in the form of a combination with a phosphoric acid, a common normal component of animal tissues; in calcium carbonate, calcium is also present as the salt of an acid of widespread occurrence in living tissues. In both cases, the calcium is split off from the acid during the process of digestion, and is absorbed into the body in the same form in each case.

Effect of Cooking on Vitamins

VITAMINS are lost or destroyed in the preparation and cooking of greenstuffs by many of the methods now in common use. Some generalizations which summarize our knowledge of the behaviour in greenstuffs of the vitamins most likely to be affected in the course of preparing green vegetables for the table have been issued by the Accessory Food Factors Committee of the Medical Research Council (London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1). Some simple rules based on these generalizations are given and cooking methods for greenstuff are recommended. Fat-soluble vitamin A is unlikely to suffer damage; water-soluble vitamins B and C are the most likely to be lost in preparation and cooking for various reasons stated. Twelve practical rules for the conservation of vitamins in the preparation and cooking of green vegetables are also given, together with methods recommended which result in the least loss of vitamin C.

War Food Production Advisory Bulletins

THE Welsh Plant Breeding Station, Aberystwyth, has issued two further War Food Production Advisory Bulletins, No. 2, "Ley Farming" by Sir George Stapledon, and No. 3, "Herbage Seed Production" by G. Evans (price 1*s*. each). These publications are complementary one to the other, the first being an extension of the first bulletin of the series, while the second shows the farmer how he can raise the necessary seeds himself. After a general description of the nature of ley farming and how it differs from the permanent grass or the grass-arable systems, six methods of dealing with permanent grass are suggested which show how the change over to ley-farming can be effected from all grades of land. Care is taken to indicate where manures, particularly phosphates, can be most profitably applied. As regards seed production, the directions are based on the author's experiences in inspecting farms and conducting experiments in various parts of Great Britain, and there seems no reason why more farmers should not successfully raise their own seed than have done so in the past. A full knowledge of the recent history of the fields and adequate provision for their isolation are two essentials for the production of pure strains; climate and soil are also important, the former especially in the case of the clovers, while grasses make larger demands on the soil. Practical recommendations are given as regards sowing, manuring, times of harvesting, threshing, cleaning and storing, together with the yields likely to be obtained. The bulletin concludes with a list of the herbage strains bred by the station at Aberystwyth and a description of their special characteristics.

Town and Country Planning

THE forty-second annual report of the Town and Country Planning Association refers to a memorandum on "Town Planning in Relation to the Present Emergency and After-War Reconstruction" submitted to the Prime Minister last autumn, as well as to opportunities which Sir Montague Barlow, Prof. P. Abercrombie, Dr. W. A. Robson and other members have had of putting before Lord Reith and Mr. Arthur Greenwood the policy of national planning, decentralization, re-development and construction of new towns for which the Association stands. The

agreed findings of the report of the Royal Commission on the Geographical Distribution of the Industrial Population are substantially consistent with evidence given before the Commission by the Association and have proved of the utmost value as a basis for national policy. The Council is considering what forms of activity are practicable in present circumstances to use the new opportunities. The formation of groups, in as many towns as possible, which will undertake research and education in the local application of a national planning policy, is desirable. There is a great demand from men in the services and civilian groups for well-informed talks and booklets on future planning. Much also needs to be done to develop sound policy and technical knowledge among members of local authorities and their staffs. The report also directs attention to the change in name of the Association from "The Garden Cities and Town Planning Association", and includes a short statement of town–country planning principles, adopted by the Council in January 1941, acceptance of which by the Government and Parliament is urged.

These suggestions include the establishment of a Ministry, advised by a National Planning Council, to guide future development and re-development, and the future grouping of industry and population, to secure the best use of the land and to conserve the national resources in the general interest. The distinction between town and county should be maintained in all development, and sporadic building in rural areas discouraged. In particular, good food-growing land, places of special landscape beauty, and areas suitable for national parks or coastal reservations should be protected from ordinary building development. Good design and lay-out of buildings and roads as well as sound construction should be an object of policy. In rebuilding urban areas, the density of residential districts should be limited to provide sufficient open space, including reasonable garden space, and wide country belts should be reserved around all cities and towns. New developments required by industrial changes, decentralization from congested areas, or by the growth of towns up to their planned limits should be directed to other towns or to new towns carefully sited and planned. The Ministry charged with national planning should have power to prevent, except under licence, the settlement of new industrial undertakings in overgrown or congested towns and in undeveloped rural areas, and to offer inducements to industry to settle in suitably selected places. The inadequate provisions for compensation and betterment under the Town and Country Planning Act should be replaced by new legislation based on expert consideration before the conclusion of the War.

Soil Mechanics in Brazil

AMONG the papers contributed to the Third Reunion of the Brazilian National Laboratories for Testing Materials was one on soil stabilization, which has since been issued as a booklet by the National Institute of Technology, Rio de Janeiro. The author, Paulo Sá, outlines existing knowledge in this branch of the science of soil mechanics, in the hope of directing the attention of Brazilian engineers to this new and important science. This would be a commendable aspiration in any country. Too many engineers are unfamiliar with the extent to which the study of foundation and earthwork problems has been developed during the last ten or twenty years, for it is now legitimate to speak of the emergence of a rational science of soil mechanics, based on sound scientific principles and making full use of theory, experiment and practice. Here again, as in most cases of fresh scientific approach to an old problem, research has established a considerable lead on practical application. The Brazilian writer complains that, in his country, soil mechanics specialists are *muito poucos*: in Great Britain also they are all too few. But the subject is not only a matter for the specialist. It should become part of the training of all civil engineers. Emphasis has been laid on the need for greater attention to it in Great Britain in annual reports of the Building Research Board which, in its report for 1938, noted with satisfaction steps taken at several university institutions, following a conference at the Building Research Station, to bring the subject into greater prominence in the curriculum for engineering students.

Electric Heating in the Pottery Industry

THE new pottery factory of Messrs. Josiah Wedgwood and Sons, Ltd., at Barlaston, has been described in articles in the *Electric Review* of April 18 and May 2. For the first time in Great Britain, electrical biscuit and glost firing have been combined in one kiln. In biscuit firing the pottery is subjected to direct radiation from the source of heat instead of being stacked in the kiln in special containers (saggars). Both the biscuit and glost firing are effected in a double tunnel kiln of the conveyor type. The two tunnels—one biscuit and one glost—are side by side, so as to reduce construction costs and effect a measure of heat recuperation. In each tunnel there are a heating-up and a cooling-down section at opposite ends of the firing zone, and the sequence in the case of biscuit firing is opposite to that of glost firing. The overall length of the kiln is 272 ft. and the firing zone is about 100 ft. long. Each tunnel measures about 6 ft. by 4 ft. inside, just a little larger than the trucks which convey the wares through the kiln. The firing zone of each tunnel has a number of sections, the temperatures of which, as recorded by pyrometers on the outside walls and at the centres of the sections, follow a desired curve in each case, with a maximum in the case of biscuit firing of about 1,150° C. 'Kanthal' type or aluminium-iron elements consisting of strip about ½ in. wide wound spirally on a refractory former about 3 ft. long are used. Trucks carrying the pottery run on rails continuously through the kiln end to end as a train, the whole being propelled by a pusher unit, which operates with the end truck at the tunnel entrance. Enamelling firing for colour work demands a temperature of about 850° C., which

is low in comparison with biscuit and glost firing. The enamel firing is also done electrically, but this is not a new development although the kiln used for the purpose is new.

Jean Nicolas Corvisart (1755–1821)

In a recent paper (*Proc. Roy. Soc. Med.*, **34**, 239; 1941) on the life and times of Jean Nicolas Corvisart, after emphasizing the resemblance between the stirring events at the beginning of the nineteenth century and those at the present time, Dr. Halls Dally said that the genius of Laennec had almost eclipsed the glory of his teacher Corvisart, whom several biographers merely regarded as "First Physician to the Emperor Napoleon I". Corvisart, however, had greater claims to medical fame. He rescued the art of percussion invented by Auenbrugger from oblivion, perfected it, and was the father of cardiology. His great work on diseases of the heart and great vessels, which was published in 1806, marks the beginning of the clinical study of cardiology. His numerous distinguished pupils and successors included Bichat, the founder of biology, Bretonneau who discovered diphtheria, Bouillaud who first described the cardiac manifestations of rheumatic fever, Dupuytren who created the school of clinical surgery and Cruveilhier, the celebrated anatomist and pathologist.

Recent Earthquakes

A severe earthquake just before noon G.M.T. on June 26 had its epicentre near the Nicobar Islands in the Bay of Bengal, north-west of Sumatra. It is not yet known how many casualties or how much damage was caused, but only twelve of these British governed islands are inhabited. The amplitudes caused by the earthquake on the seismographs throughout the world were comparable to those caused by the Quetta and Turkish earthquakes.

Earthquakes on the same day were experienced in eastern Morocco causing considerable damage but few casualties.

The U.S. Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association has calculated the provisional epicentres of the earthquakes of April 1, 3 and 7. The first was south of the Alaskan Peninsula near 56·0° N., 153·0° W., at 10h. 41·1m. G.M.T. The second was in Chile near 25° S., 69° W. at 15h. 21m. G.M.T. with a depth of focus near 200 km. The third was in the Caribbean Sea south of Jamaica near 17·6° N., 78·3° W. at 23h. 29·3m. G.M.T. All are in well-known seismic regions.

Institute of Fuel: Students' Medal

To encourage the preparation of papers by students of fuel technology, the Council of the Institute of Fuel has decided to make an annual award of a medal, together with a prize consisting of books and/or instruments to the value of £5, for a paper submitted by a student member of the Institute or by a student less than twenty-five years of age of any university or technical college in the United Kingdom. The paper must deal with some subject relating to the preparation or utilization of fuel, or allied subjects. Papers must be submitted to the Secretary of the Institute under a *nom de plume*, the name and address of the author being enclosed in a sealed envelope and sent with the paper, and must be received by the Secretary on or before September 1 in any year. Further particulars can be obtained from the Secretary, Institute of Fuel, 30 Bramham Gardens, London, S.W.5.

Announcements

The Academy of Sciences of the U.S.S.R. has awarded the Pavlov Prize for 1940 to Prof. Maria K. Petrowa, professor at the Pavlov Institute of Physiology.

The Royal Swedish Academy of Science has elected Sir Thomas Lewis, physician-in-charge of the Department of Clinical Research at University College Hospital, London, a foreign member of the Faculty of Medical Research.

Miss Julia Bell, honorary Galton research fellow of University College, London, and member of the scientific staff of the Medical Research Council, has been awarded the Weldon Memorial Prize for 1941 of the University of Oxford.

Mr. Griffith Brewer has been elected president of the Royal Aeronautical Society for the year October 1941–September 1942; Prof. L. Bairstow, Mr. W. C. Devereux and the Right Hon. J. T. C. Moore-Brabazon have been elected vice-presidents for the same period.

Prof. Carl Neuberg, formerly professor in biochemistry in Berlin, Amsterdam and Jerusalem, has been appointed professor of biochemistry at the New York University College of Arts and Science.

The title of honorary reader in organic chemistry in the University of Leeds has been conferred upon Dr. J. W. Baker, lecturer in the Department of Organic Chemistry. Mr. T. G. Bridgwood has been appointed lecturer in electrical engineering.

The Council has agreed, on the recommendation of the Senate, that in general all men students of the University of seventeen and above should be required to become (if not already) members of the Senior Training Corps or the Air Training Squadron, or alternatively to undertake some other form of national service approved for the purpose.

A research scholarship of the value of £250 per annum and tenable for two years has been founded by the Wrought Light Alloys Development Association to encourage and facilitate research in the application of light alloys to ship construction. The scholarship will be administered by a committee of the Institution of Naval Architects and it is hoped to make the award in September 1941. Full particulars of entry, which closes on July 31, can be obtained from the Secretary, Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1.

A New Method for the Estimation of Trigonelline in Urine and Foodstuffs

THE recognition of trigonelline as a product of the metabolism of nicotinic acid is due to Ackermann[1], who in 1912 dosed dogs with nicotinic acid and found it to be partly excreted as trigonelline. Linneweh and Reinwein[2,3] isolated the latter substance from normal human urine, and found that the amount excreted was increased after the consumption of coffee. More recently Sarett, Perlzweig and Levy[4] reported that when human subjects were dosed with nicotinic acid, a portion of it, ranging from 10 to 15 per cent, was excreted as trigonelline. Melnick, Robinson and Field[5] have made similar observations. However, the exact relation between the excretion of trigonelline and intake of nicotinic acid remains to be investigated, and can only be settled after a satisfactory quantitative procedure for the estimation of trigonelline has been devised. The methods used by Sarett and his co-workers and by Melnick *et al.*, involve the conversion of trigonelline to nicotinic acid in the presence of strong alkali and ammonia. The conversion according to the former group of workers is 65–75 per cent, and according to the latter group 28–38 per cent. The amount converted seems to depend on the concentration of ammonium salts, the strength of alkali used, the length of hydrolysis, and possibly other factors, and the method at best is only semi-quantitative.

We have devised a new quantitative method for estimating trigonelline in urine and foodstuffs, based on the observation that when trigonelline is hydrolysed with alkali in alcoholic solutions, methylamine is split off, leaving the ring open. The resulting product can be combined with aromatic amines to give coloured compounds which can be measured quantitatively. Of a number of amines examined, we found benzidine to be the most satisfactory. It gives an orange-red derivative with the hydrolysed product, which seems to be specific for trigonelline. Pyridoxine (vitamin B_6), nicotinic acid, nipecotic acid and nicotine show no such reaction. The only other compound, so far as we are aware, which reacts similarly is *N*-methyl pyridinium hydroxide. By this method, $1 \cdot 0$ μ gm. of trigonelline per ml. of urine can be quantitatively estimated. The average recovery of added trigonelline to urine from eighteen trials was 95 per cent ($\pm$ 8 standard deviation). The procedure is as follows:

For urine: To 10 ml. of urine add ½ ml. of 40 per cent sodium hydroxide and heat on a boiling water-bath for twenty minutes. Cool, add 1 ml. of concentrated hydrochloric acid and 0·4 ml. of 10 per cent barium chloride solution, and then 40 ml. of 96 per cent ethanol. Add 0·5 gm. of Norite charcoal and shake for one minute. Filter and measure two 20 ml. portions of the filtrate into two 50 ml. conical flasks. To one of the flasks add 0·5 ml. of a standard trigonelline solution containing 50 mgm. per ml. Add 4·2 ml. of 40 per cent sodium hydroxide to each flask and heat on the water-bath for ½ hour. Cool, neutralize cautiously, and make up to 30 ml. Centrifuge, and measure two 10 ml. portions of the centrifugate into two test tubes, one for the blank and the other for the unknown. The blank should contain 1 ml. of 5 per cent hydrochloric acid, and the unknown 1 ml. of 1 per cent benzidine in 5 per cent hydrochloric acid. Allow one hour for the colour to develop, and then measure the colour in a Pulfrich photometer using filter number *S* 50.

For foodstuffs: With foodstuffs the preliminary digestion for twenty minutes is omitted. Measure 10 ml. of an extract of the material into a conical flask and treat with hydrochloric acid and barium chloride, and proceed as described above. In coffee and tea, 7·5 mgm./gm. and 0·13 mgm./gm. of trigonelline respectively were found.

The accompanying table shows some of the typical results obtained with urine.

EXCRETION OF TRIGONELLINE AND NICOTINIC ACID* BY A NORMAL INDIVIDUAL ON A COFFEE-FREE DIET AND AFTER DOSING WITH 50 MGM. AND 100 MGM. OF NICOTINIC ACID.

Description	Trigonelline excreted		Nicotinic acid excreted		Nicotinic acid + trigonelline total
	In mgm. per day	Increased excertion as % of nic. acid dosed	In mgm. per day	Increased excretion as % of nic. acid dosed	Increased excretion as % of nic. acid dosed
1st day—normal coffee-free diet	14·1	—	1·3	—	—
2nd ,, ,, ,, ,, ,,	11·0	—	1·1	—	—
1st day + 50 mgm. nicotinic acid	20·6	16·0	2·7	3·0	19·0
2nd ,, ,, ,, ,, ,,	21·5	18·0	2·2	2·0	20·0
1st day + 100 mgm. nicotinic acid	21·0	8·4	10·9	9·7	18·1
2nd ,, ,, ,, ,, ,,	34·3	31·7	11·3	10·1	41·8
3rd ,, ,, ,, ,, ,,	35·0	22·4	7·9	6·7	29·1
4th ,, ,, ,, ,, ,,	47·9	35·3	9·6	8·4	43·7
5th ,, ,, ,, ,, ,,	46·3	33·7	—	—	—
6th ,, ,, ,, ,, ,,	41·7	29·1	—	—	—

* By the modified method of Harris, Kodicek and Wang[6].

The excretion of trigonelline by normal individuals on a coffee-free diet ranged from 10 to 16 mgm. per day. After dosing with nicotinic acid the increased output of trigonelline varied from 10 to 28 per cent of the ingested dose, depending upon the size of the dose and the body weights of the subjects.

The metabolic connexion between trigonelline and nicotinic acid is of interest in relation to the test proposed for assessing the nutritional status of human subjects in the anti-pellagra vitamin (Harris and Raymond, 1939[7]). This depends on the measurement under controlled conditions of the urinary excretion of nicotinic acid or related substances. We have confirmed the conclusion of Harris and Raymond[7] that their method does measure essentially the nicotinic acid (which is biologically active), and that trigonelline (which is inactive), does not interfere. With the low concentration of alkali and the short period of hydrolysis used, no detectable amount of trigonelline is converted to nicotinic acid. The disadvantage of a prolonged digestion with stronger alkali, as used by Swaminathan[10], is that a considerable conversion of trigonelline into nicotinic acid occurs. The method of alkaline hydrolysis used by Harris and Raymond seems preferable to that of acid hydrolysis used by Melnick and Field[8], since the latter may involve an incomplete conversion of nicotinuric acid, and a darker digestion mixture. Also Melnick and Field[9], in criticizing the blank correction, seem to have overlooked the fact that the Cambridge workers employed an acid reaction medium, in which the urine reacts less with interfering substances than in the neutral medium used by Melnick and Field, and in which the bleaching effect of CNBr is entirely suppressed.

We have introduced certain modifications in the method of analysis which increase its sensitiveness and accuracy; these include the removal of interfering substances by preliminary adsorption on charcoal, control of period of hydrolysis and adjustments in the blank correction.

In conjunction with Dr. Harris we have confirmed again that the estimation of nicotinic acid, as such, in urine, in the absence of test-dosing (that is, measurement of 'resting level' of excretion) does give an indication of the past intake of nicotinic acid and hence of the anti-pellagra status of the subject: thus in deficiency in humans, in dogs and in guinea pigs the excretion of nicotinic acid falls either to zero or to a very low level[6]. Indeed, in ordinary circumstances it seems preferable to estimate the nicotinic acid rather than the trigonelline in a specimen of urine, because, unless special precautions have been taken to make the diet free of trigonelline, it may be excreted in large amounts as such in the urine, even when there has been no nicotinic acid in the diet and the subject is actually deficient. For test-dosing on the other hand ('saturation tests') the most satisfactory procedure would appear to be to administer nicotinamide and estimate both the trigonelline and the nicotinic acid excreted while the subject is kept on a controlled diet low in trigonelline. Our reason for this recommendation is the finding that when doses of nicotinic amide are given the product excreted in the urine is almost entirely trigonelline, while with a nicotinic acid dose both trigonelline and nicotinic acid (or nicotinic acid-like substances) are found. The possible explanation may be that nicotinic acid given by mouth has first to be converted by the organism into nicotinamide before being excreted as trigonelline, and any excess which escapes this conversion will be excreted as nicotinic acid-like substances. On the other hand, nicotinamide is utilized as such and there is no overflow of nicotinic acid-like substances, but only an increased excretion of trigonelline.

Sulphanilylguanidine

IN view of the present interest in the trial of sulphanilylguanidine for the treatment of bacillary dysenteries[1] it may be useful to direct attention to a convenient method for the preparation of this substance by the fusion of sulphanilamide with dicyandiamide which we described some years ago. In our original description of this reaction[2] it was assumed that the substance isolated was formed by the addition of the cyanamide group at the N4 position to give 4-sulphonamidophenylguanidine; $NH:(NH_2)CNHC_6H_4.SO_2NH_2$; actually addition takes place at the N1 position to give sulphanilylguanidine, $NH_2C_6H_4.SO_2NH.C(NH_2):NH$ completely identical with the product recently obtained by Marshall *et al.*[3] by the interaction of *p*-acetylaminobenzenesulphonyl chloride and guanidine. Marshall's synthesis leaves no doubt about the correct constitution of the substance, which is confirmed also by the insolubility of the substance in alkali and the development of colour on diazotizing and coupling.

We are much indebted to Prof. E. K. Marshall, jun., who has kindly directed our attention to the identity of the substance produced by these two reactions.

Vitamin A in Canned Salmon

IN a communication in NATURE[1], Pyke and Wright have commented on the high values for the vitamin A contents of salmon-body and salmon-flesh oils given in the tables of Fixsen and Roscoe[2]. In their own experiments they have failed to detect any vitamin A by the antimony trichloride method

in twelve specimens of canned and two of chilled salmon flesh.

While the upper values quoted by Fixsen and Roscoe certainly seem beyond the range reported by most investigators, my own experience does not support the view of Pyke and Wright that canned salmon is quite devoid of vitamin A. In four specimens purchased locally, I have found 5, 120, 120 and 150 I.U. of vitamin A per 100 gm. of flesh by the antimony trichloride method, applied to the unsaponifiable fraction. These results agree with the findings of most previous workers that canned salmon contains small but appreciable amounts of vitamin A.

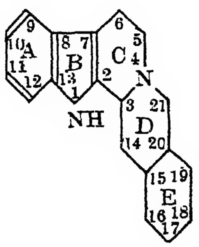
Constitution of Yohimbine

It has been suggested by D. G. Harvey, E. J. Miller and W. Robson in a recent publication[1] on the colour reactions of tryptophan and allied compounds—among them the alkaloid yohimbine—that the formation of a *blue* colour in sulphuric acid containing a trace of oxidizing agent is characteristic of the 4-carboxytetrahydro-β-carbolines. The presence in yohimbine of both tetrahydro-β-carboline and carboxylic acid (actually carbomethoxyl) residues has been recognized for some time, and it is clear from the formation in good yields of 2 : 3-dimethylbenzoic acid from ketodihydroyobyrine[2], and of harman and *m*-toluic acid from tetradehydroyohimbic acid[3], that the carbomethoxyl must be attached to the yohimbine skeleton, which is as depicted, in ring *E* at position 16.



Harvey, Miller and Robson do not, however, refer to this evidence, but conclude that the carbomethoxy-group is located at C_5 because the alkaloid displays a 'carboline-blue' colour reaction.

We have been engaged on experiments on the constitution of yohimbine, and by distilling yohimbic acid with copper and cupric oxide instead of alkali have improved Hahn's preparation of yohimbol[4]. The complete identity which we have observed between the sulphuric acid colour transformations of this *carboxyl-free* secondary alcohol and of yohimbine entirely invalidates the evidence on which the suggested alternative formula rests. With regard to the position of the alcoholic hydroxyl, which Hahn[5] disposes at C_{17}, it appears to us that the available evidence strongly favours its existence at C_{19}, and we propose for the alkaloid a structure having the groups $-CO_2Me$ and $-OH$ at positions 16 and 19 respectively.

Salaman's Culture of Blight Resistant 'Aya papa'

A FURTHER note may be of interest in connexion with Reddick's paper, "Whence came *Phytophthora infestans*?"[1], on the question of the distribution of blight resistant potatoes in the American continent.

Blight resistance has so far been found only in Mexico with the exception of a plant known as 'Aya papa' from Ecuador. Salaman's culture of this plant is immune, but Reddick considers that this is not the original Aya papa collected by P. T. Knappe but a *Solanum demissum* hybrid in about the first back-cross stage.

Cytological examinations of root tip preparations made by us from Salaman's Aya papa show that the specimen is a pentaploid with 60–62 somatic chromosomes. The chromosome number thus confirms Reddick's suggestion that Salaman's culture of Aya papa is a hybrid between *S. demissum* ($2n = 72$) and *S. tuberosum* ($2n = 48$). The plant also shows many morphological similarities to *S. demissum*, especially in such floral details as the short corolla lobes and characteristic 'star'.

We were at first inclined to consider that Knappe's original plant was also a *S. demissum* hybrid, but both Bukasov (see Reddick[1]) and Black (in a private communication), who obtained their cultures direct from Knappe, found it to be susceptible. Furthermore, their descriptions (Bukasov[2], Black, in a private communication) do not agree with Salaman's culture. A further piece of evidence comes from Ecuador itself. One of us (J. G. H.) when in Riobamba (whence Knappe was said to have obtained his tubers of Aya papa) was able to ascertain that potatoes known as Aya papa did actually occur in certain localities, growing apparently wild in the vicinity of native habitations and villages. They are regarded by the Indians as potatoes which were cultivated by their ancestors—hence the Quechua name 'Aya', which means 'dead person, ghost or ancestor' and 'papa', signifying 'potato'.

All evidence, therefore, points to the conclusion that Knappe's Ecuadorean potato was not blight resistant and that this quality has not yet been discovered outside Central Mexico.

The Recombination Law for Weak Ionization

IN order to explain the observed relation between the number of condensation nuclei in atmospheric air and the ionization, an equilibrium equation was proposed[1] of the type $q = an + bnZ$, where q is the rate of production of ion-pairs per cm., n and Z the concentrations of small ions (of one sign) and nuclei, and a and b are constants for any given conditions. This implies that, in atmospheric air, the rate of loss of ions by recombination among themselves is proportional to n and not to n^2. It was suggested that, where a volume of air is traversed at any time by only a few ionizing particles, the rate of loss of ions from the space by recombination is proportional to the number of ion tracks and hence approximately to n.

To test this view, experiments have been carried out on air free from nuclei contained in a vessel of volume 730 litres. The intensity of the ionization inside the vessel was varied by placing a small quantity of radium at different distances from it. Observations were made of n for different values of q. In experiments of this kind, ions are lost by diffusion as well as by recombination, and the chief difficulty is to make a proper allowance for this loss. In this work, correction for diffusion has been made on the lines developed by Power[2], and it is believed that the corrected values of n are fairly accurate.

Using corrected values of n, and plotting log n against log q, we obtain a graph the slope of which varies. For values of q between 360 and 120, the slope is 2·0, in agreement with the ordinary law $q = \alpha n^2$. For lower values of q the slope becomes less. For values of q between 30 and 12, it is approximately 1·45. Experiments in the range $q < 12$ have not as yet been possible. Putting the law in the form $q = kn^p$, the experiments indicate a considerable diminution in the value of p over the range of observation. It is possible that with lower values of q, p may approach to unity, giving the linear recombination law proposed to explain the equilibrium of ionization in the atmosphere.

It is perhaps worthy of note that in the region where the law $q = \alpha n^2$ appears to hold, the calculated value of α is $1{\cdot}56 \times 10^{-6}$, which is closer to the values obtained by the earlier workers than to the more recent values such as that of Sayers[3].

Surface Films of Polar Crystals

THE study of atomic monolayers was initiated by Miss Pockels and the late Lord Rayleigh long ago, for capillary surfaces. It was capable of extension to electric crystalline structure, on the basis of the analysis of local polarization which is to be found in Maxwell's "Treatise" but is usually quoted under the names of Clausius and Lorentz. It compels the result that for a crystal polarized transverse to its surface a monolayer of compensating ions is required on its face, but in number *half* that in each ionic sheet of the crystal[1].

I have looked for a long time for some confirmation of so remarkable a result. The fundamental discovery of the diffraction of uniform pencils of electrons at the surface of a crystal, independently by Davisson and Germer in New York and by G. P. Thomson and A. Reid in Aberdeen, gave promise in this direction. This subject has now grown into an immense technical science with which only experts can be familiar, as is illustrated in the recent treatise by G. P. Thomson and W. Cochrane[2]. In turning over its pages I have hit upon the confirmation which I wanted, relating to the surface film, in a passage (p. 270) here reproduced, on the diffraction of pencils of slow electrons. It describes results reported in Davisson and Germer's early memoir.

"The new beams . . . thus possess the character of plane- rather than space-grating beams. Measurement shows, however, that the plane-grating spacing to which they correspond is in each case exactly twice that of the nickel atoms in the azimuth in question."

I have, however, not succeeded in explaining the concept of an index of refraction of the electrons along such lines.

Flow Properties of Some Thermoplastics

Scott Blair and Coppen[1], dealing with the compression of cylinders under constant stress, have given a general method of specifying the rheological properties of plastic materials by making use of two characteristics ψ, k given by

$$\psi = s\sigma^{-1} t^k, \quad . \quad . \quad . \quad (1)$$

where s, σ, t have their usual meaning. Broome and Bilmes[2] have confirmed the validity of the treatment by their work on the stretching of asphalt strips.

Scott Blair[3] had previously suggested a modification of the Bingham-Murray equation for the emptying of an initially full capillary tube, instead of the usual filling of an empty one. For the case of materials not obeying Poiseuille's law, he suggested a parabolic plot of the data obtained. Fundamentally, as applied to the original Bingham-Murray method, this modification can be expressed by

$$\Psi = \frac{PR^2}{4} \cdot \frac{1}{h^2 - h_0{}^2}\, t^K, \quad . \quad . \quad (2)$$

where P is the pressure, R the radius of capillary, h the length of extrusion, t the time, and h_0 is the extrusion at time $t = 0$, and the exponent K "differs from unity to an extent which is the measure of the discrepancy from truly fluid behaviour". When $K = 1$, Ψ corresponds to a true viscosity. There is a formal similarity between equations (1) and (2).

The value of the stress averaged across a diameter of the tube is $PR/4h$. From a comparison of the differential form of the Bingham-Murray equation

$$\frac{d}{dt}\left[\frac{2h}{R}\right] = \frac{1}{\eta}\,\frac{PR,}{4h} \quad . \quad . \quad . \quad (3)$$

with the equation defining the viscosity, η,

$$\frac{d\sigma}{dt} = \frac{1}{\eta}\, s, \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

we see that $2h/R$ can be regarded as the value of the strain averaged across a diameter. Using this ex-

	Thermoplastic	K	Ψ
I	Tenite I (M.S.)	1·0	$1{\cdot}17 \times 10^3$
II	Tenite II (M.)	0·74	$1{\cdot}35 \times 10^3$
III	Cellulose Acetate, low plasticizer content	0·57	$9{\cdot}55 \times 10^3$
IV	Polystyrene	0·54	$1{\cdot}60 \times 10^3$

pression for the strain, and defining Ψ by the equation

$$\Psi = s\left[\frac{d\sigma}{dtK}\right]^{-1}, \qquad . \quad . \quad . \quad . \qquad (5)$$

we obtain (2) by direct integration. Equation (5) is, in effect, the Scott Blair and Coppen equation (1) adapted to differential analysis.

For constant pressures we have found that plots of $\{\log(h^2-h_0^2), \log t\}$ give straight lines in the case of many thermoplastics, and thus reveal K.

Then

$$\log \Psi = \log \frac{PR^2}{4} + K - \log (h_{10}{}^2 - h_0{}^2)$$

where h_{10} is the extrusion after 10 seconds.

Since the average stress $PR/4h$ falls off as the flow proceeds, there is no suggestion that the conditions for a basic analysis of flow (that is, constant stress) are being satisfied. The above treatment, however, seems well suited to the specification of the flow properties of thermoplastics. Further investigation along these lines is in progress.

We have to thank the directors of the British Xylonite Co., Ltd., for permission to publish this note.

'Shot Effect' in Temperature-Limited Diodes

THE 'shot effect' in temperature-limited (saturated) diodes has certain similarities with the 'Johnson effect' observed in electrical resistances. Though the classical formula of the shot effect may be derived in several different ways, to my knowledge it has not yet been done on the same lines as those used for obtaining a formula for the Johnson effect. J. Bernamont[1] has shown that the 'Johnson effect' formula, namely, $\bar{e}^2\nu = 4RkT$, may be obtained in the electronic theory of metals, using either the Lorentz or Sommerfeld theory of conductivity. The purpose of this note is to show that, following Bernamont's method for the Johnson effect, one may derive the classical formula of the shot effect.

Let $f(u)S.dx.du$ be the number of electrons in the volume element $S.dx$, dx being the length of the trajectory of an electron the velocity of which lies between u and $u + du$, and S the emitting area of the filament. Owing to the Maxwellian distribution of the electrons emitted by the filament, we have:

$$f(u)du = n2hme^{-hmu^2}du,$$

with $hmu_c{}^2 = 1$ and $1/2mu_c{}^2 = kT$, where T is the temperature of the filament. An electron of velocity u is equivalent to a current element the length of which is dx, and:

$$\delta j dx = u\varepsilon,$$

ε being the electron charge.

The mean square of the current is then:

$$\overline{j^2} = Sdx\int_0^\infty \frac{\varepsilon^2 u^2}{dx^2} f(u)du.$$

M. Courtines[2] has shown that the 'correlation function' of the current in a saturated diode is, where θ is the time of correlation,

$$\begin{cases} \overline{ii_t} = \dfrac{\theta - |t|}{\theta}\overline{j^2}, & \text{for } |t| \leq \theta \\ \overline{ii_t} = 0 & \text{for other values of } t. \end{cases}$$

The 'spectral component of intensity' of a function y, for 'infinitely brief' correlation, that is, for frequencies ν satisfying the relation $\nu << 1/\theta$ is[1]:

$$\overline{y_\nu{}^2} = 4\int_0^\infty \overline{yy_t}dt,$$

whence:

$$\overline{i_\nu{}^2} = 4S\varepsilon^2\int_0^\infty \frac{1}{dx}\cdot f(u)u^2du\int_0^\infty \frac{\theta-|t|}{\theta}\,dt,$$

and

$$\overline{i_\nu{}^2} = 2S\varepsilon^2\int_0^\infty \frac{\theta}{dx}\cdot f(u)u^2du.$$

Now:

$$\theta/dx = 1/u, \text{ and } \overline{i_\nu{}^2} = 2S\varepsilon^2\int_0^\infty f(u)udu;$$

so that

$$\overline{i_\nu{}^2} = 2S\varepsilon^2 n.$$

But

$j = S\varepsilon n$ is the mean diode current; hence finally:

$$\overline{i_\nu{}^2} = 2\varepsilon j.$$

PHYSICAL INTERPRETATION OF QUANTUM MECHANICS*

By PROF. P. A. M. DIRAC, F.R.S.

MODERN developments of atomic theory have required alterations in some of the most fundamental physical ideas. This has resulted in its being usually easier to discover the equations that describe some particular phenomenon than just how the equations are to be interpreted. The quantum mechanics of Heisenberg and Schrödinger was first worked out for a number of simple examples, from which a general mathematical scheme was constructed and afterwards people were led to the general physical principles governing the interpretation, such as the superposition of states and the indeterminacy principle. In this way a satisfactory non-relativistic quantum mechanics was established.

In extending the theory to make it relativistic, the developments needed in the mathematical scheme are easily worked out, but difficulties arise in the interpretation. If one keeps to the same basis of interpretation as in the non-relativistic theory, one finds that particles have states of negative kinetic energy as well as their usual states of positive energy, and, further, for particles the spin of which is an integral number of quanta, there is the added difficulty that states of negative energy occur with a negative probability.

* Substance of the Bakerian Lecture of the Royal Society, delivered on June 19.

With electrons the negative-probability difficulty does not arise, and one can get a sensible interpretation of the negative-energy states by assuming them to be nearly all occupied, and an unoccupied one to be a positron. This model, however, is excessively complicated to work with and one cannot get any results from it without making very crude approximations. The simple accurate calculations that one *can* make would apply to a world which is almost saturated with positrons, and it appears to be a better method of interpretation to make the general assumption that transition probabilities obtained from these calculations for this hypothetical world are the same as those for the actual world.

With photons one can get over the negative-energy difficulty by considering the states of positive and negative energy to be associated with the emission and absorption of a photon respectively, instead of, as previously, with the existence of a photon. The simplest way of developing the theory would make it apply to a hypothetical world in which the initial probability of certain states is negative, but transition probabilities calculated for this hypothetical world are found to be always positive, and it is again reasonable to assume that these transition probabilities are the same as those for the actual world.

OBSERVATIONS MADE AT THE ROYAL OBSERVATORY, GREENWICH

THE observations made during 1936 at the Royal Observatory, Greenwich, have just recently been made available*.

The work is divided into five sections, the first of which, Section A, Meridian Astronomy, contains three subdivisions. Under (1), Transit Circle, 1936, the observed right ascensions, declinations and diameters of the sun, moon and planets are given and compared with the corresponding results as given in the "Nautical Almanac." These tabular places are derived from the well-known tables of Newcomb, Brown and Hill. The mean monthly corrections to Newcomb's place of the sun as given in the "Nautical Almanac" are shown, and also the corrections in longitude and latitude to Brown's "Tables of the Moon". These are deduced from the observed corrections to the right ascension and declination, the mean correction to the former being $0 \cdot 15^s$, corresponding to $2 \cdot 2''$ in mean longitude. Under (2), Time Service, is included a brief description of the reversible Transit "B" which was remounted on January 24, 1935, its place having previously been taken by Transit "D" on April 7, 1933. Collimation is eliminated by reversing the instrument on all stars, and observations are carried up to approximately 20^s of the meridian. Eighteen contacts are observed in each position of the instrument, when possible, and each signal is read to $0 \cdot 01^s$. Table II gives details of observation of clock corrections, and comparisons of Clocks Shortt Nos. 3 and 11 appear in Table V. The Greenwich time determinations are regularly compared with those of other observatories by the reception of wireless signals and the results are given in Table VIII. Under (3), Variation of Latitude, it is pointed out that as the Cookson floating zenith telescope was moved in 1936 to the Christie enclosure and remounted, a new observing programme being introduced at the same time, the results for the latitude variation given by the instrument will not be published for some time. The values of the latitude variation taken from the results of the International Latitude Service are given, and these have been used in the Transit Circle reductions.

Section B, Equatorial Observations, contains the results of the observations of double stars made with the 28-inch refractor. The list deals with the first observations carried out on the programme drawn up in 1936; the pairs were selected from Aitken's "New General Catalogue of Double Stars." These pairs were chosen on the following grounds:

* Observations made at the Royal Observatory, Greenwich, in the Year 1936, in Astronomy, Magnetism and Meteorology, under the direction of Dr. H. Spencer Jones. Pp. viii+A78+B16+Cix+161+D66+E46+38. (London: H.M. Stationery Office, 1939.) 35s. net.

(1) rapidly moving pairs for which orbits have been computed or will be computed within a few decades; (2) pairs which, though not moving rapidly, nevertheless deserve an observation in the present decade, either because they are known to have a slow motion or because they may be neglected pairs.

Section C, Photoheliographic Observations, gives the positions and areas of sunspots and faculæ for each day in the year 1936. Photographs from three observatories were used. Those obtained at the Royal Observatory, Greenwich, were taken with the Dallemeyer photoheliograph of 4 in. aperture, usually stopped down to 2·9 in., and, in a few cases, with the Thompson photoheliograph of 9 in. aperture. The diameter of the sun's image at the secondary focus in both instruments is 7½ in. at the earth's mean distance. The photographs from the Cape Observatory were taken with a Dallmeyer photoheliograph giving an image of the sun about 7½ in. in diameter. Those obtained at Kodaikánal were taken with a Cooke photovisual object-glass of 6 in. aperture, the image of the sun being on nearly the same scale. This section also gives a general catalogue of groups of sunspots for 1936 and 'ledgers' of the areas and heliographic positions of groups of sunspots for 1936.

Sections D and E, Magnetic and Meteorological Observations, give a full description of the buildings and equipment of the magnetic station at Abinger and also of the results of the magnetic observations, followed by a corresponding description of the meteorological apparatus and the results of the observations.

CONCRETE IN SEA WATER

THE current issue of the *Dock and Harbour Authority* contains the reproduction from the *Proceedings of the American Society of Civil Engineers* of a paper by Homer M. Radley in which the author gave a statement of the conclusions he has reached as a result of extended observation of concrete marine structures along the Pacific coast of the United States and Canada. Contrary to the widely held view that decomposition of concrete in sea water must necessarily occur as a result of the chemical action of sulphate of magnesium, he states that, over a long period no evidence of any attack of this nature was found, and he holds that such deterioration as occurs is due to other causes.

Arguing from the characteristic form and manifestation of attack by magnesium sulphate as advanced by Vicat, he concludes that, if this occurred in the manner described, exposure to full sea-water action for a period of twelve or fifteen years should produce distinct evidence of porosity or disintegration. His investigation showed, on the contrary, that concretes made with many brands of Portland cement continue after fifteen or more years of service to exhibit the original wood-grain and other marks of the shuttering used in construction. He points to several other causes of disintegration and disruption —the rise and fall of the tides and the alternate wetting and drying of the concrete surface, mechanical blows and abrasion from flotsam and drift, and the action of storm waves and the grinding of the boulders which they toss about. Deficiencies in the quality and structure of the concrete are responsible for the most characteristic forms of deterioration, weak concrete being readily abraded, honeycombed areas becoming cavitated, laitance seams giving rise to extended voids and so on. In these respects he finds little to choose between fresh water and salt water, and contends that the same qualities which give resistance in the one are good in the other. Associated with salt water there is, however, the scaling and disruption which arise from the crystallization of salt in the exposed upper parts. These several aspects of deterioration are discussed in considerable detail, and many photographs illustrate the different types noted.

THE IMPERIAL CANCER RESEARCH FUND

BY DR. E. BOYLAND

THE thirty-eighth annual report of the Imperial Cancer Research Fund was presented to the general meeting of governors in April. New work on the nature and cause of cancer has been carried out in the Fund's laboratories at Mill Hill. In addition to this normal work, Miss Ida Mann and Dr. B. D. Pullinger have carried out experiments on the effect of ascorbic acid in mustard gas burns of the eye, and on other problems for the Ministry of Supply. Several members of the staff have been absent on war service and, although the volume of research is perhaps not so large as in normal years, work of interest and real value has been accomplished.

Histology is still an important and essential branch of cancer research. Without the microscope it would often be difficult or impossible to determine whether tumours were malignant or not. Dr. L. Foulds has written a critical review on the histology of tumours[1], a field in which workers in the Imperial Cancer Research Fund laboratories have made important contributions in the past.

Dr. B. D. Pullinger has extended her investigation on the specific response which is given by mouse skin to carcinogenic substances. With the carcinogenic 5:9:10-trimethyl-1:2-benzanthracene small amounts produce the response while larger amounts destroy the epithelium without producing the characteristic reactions. This result fits in with the finding of Prof. E. L. Kennaway and Prof. J. W. Cook that this substance is a more effective carcinogenic agent in dilute than in strong solutions.

Mr. H. G. Crabtree has continued his investigations

on biological effects of organic chlorine compounds. The effect of chlor compounds on the carcinogenic action of benzpyrene is rather complicated and varies with their concentration, type and time of application. Application of low concentrations of chloracetone alternately with benzpyrene to the skin of mice reduces the carcinogenic action, but if a higher concentration of chloracetone is applied after discontinuing the applications of benzpyrene, the carcinogenic action is enhanced. The effect of a series of chlor compounds can be correlated to some extent with their chemical and physical properties.

Tumours can be induced in animals either with biologically produced agents or with synthetic carcinogenic compounds. Some time ago Dr. R. J. Ludford described the transformation of normal chick fibroblasts into malignant cells induced by treating tissue cultures of fibroblasts with filtrates of fowl sarcomas. It has so far not been possible to produce an analogous change with carcinogenic compounds. Cultures of cells from pure-line mice were grown in the presence of methyl cholanthrene or 3:4-benzpyrene for times varying up to six months without producing malignant cells.

Dr. W. J. Purdy and Dr. R. J. Ludford have continued to investigate the factors present in birds with retrogressing filterable tumours. The blood of ducks in which the Fujinami tumour was retrogressing did not neutralize the corresponding virus, nor did it inhibit the growth of the tumour cells in tissue culture. Thus it has not been possible to determine the nature of circulating antitumour factors, if indeed such occur, when multiple tumours retrogress. It is probable that the action of the effect on tumours is indirect. Dr. R. J. Ludford has grown fragments of rat uterus and vagina in culture and treated the isolated tissues with œstradiol. Neither in these experiments nor in others, in which cultures of combs from chick embryos were grown in the presence of testosterone, did the hormones have any effect on growth. The hormones must therefore act indirectly.

The Fund has continued to co-operate with other laboratories and is still particularly helpful in maintaining and supplying many strains of transplantable animal tumours. During the past year the Fund has been fortunate in having received more than £17,000 in legacies; the whole of which has been added to the endowment fund.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN GEOGRAPHY at the Brighton Municipal Training College for Women—The Education Officer, 54 Old Steine, Brighton (July 12).

LECTURER IN MATHEMATICS and A WOMAN LECTURER IN GEOGRAPHY—The Principal, Derby Technical College, Normanton Road, Derby (July 12).

INSTRUCTOR IN WORKSHOP PRACTICE AND PROCESSES in the Schools of Technology, Art and Commerce (Engineering Department)—The Chief Education Officer, City Education Office, 77 George Street, Oxford (July 15).

PRINCIPAL of the Lancaster Storey Institute Technical College and Junior Technical School—The Director of Education, Education Offices, High Street House, Lancaster (July 19).

TEACHER OF ENGINEERING SUBJECTS—The Acting Principal, Technical Institute, Ashford, Kent.

LECTURER IN ENGINEERING for the Achimota College, Gold Coast—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9637).

ASSISTANT ENGINEER for the Malayan Government Public Works Service—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9306).

HEAD OF THE CHEMISTRY AND APPLIED CHEMISTRY DEPARTMENT of the Royal Technical College, Salford—The Director of Education, Education Office, Chapel Street, Salford, 3.

ASSISTANT ENGINEER in the Government of Zanzibar Public Works and Electricity Department—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9634).

MAINTENANCE ENGINEER in the Government of British Guiana Transport and Harbours Department—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9393).

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Friday, July 18

INSTITUTE OF PHYSICS (MANCHESTER BRANCH) (in the Physics Department, University, Manchester), at 7 p.m.—Dr. H. Spencer Jones, F.R.S.: "Problems connected with the Construction of Large Telescopes, with special reference to the 200-inch Instrument".*

NATURE

SATURDAY
JULY 12, 1941

NATIONAL CHARACTER

EVERYDAY assertions of differences in character between one nation and another have for long been maintained in the face of scepticism, and the scepticism has often seemed the more scientific attitude. It is as easy to show confusions, contradictions and over-simplifications in the popular conceptions as it is difficult to find scientific proof of the real differences which, in a confused way, they may be registering. What then should be the role of a scientific treatment of the question? Scepticism is scarcely enough. Differences of national character (in some sense of the term) have certainly not been disproved. That they have also not been proved may well reflect on the crudity of the sociological and scientific techniques at our service. In these circumstances it would seem that a proper function of scientific discussion is that of sympathetically clarifying the popular conceptions and showing what, at their most plausible, they would be, and in what directions scientific proof or disproof could most profitably be sought.

Some such purpose informs an address on national character given by Prof. Morris Ginsberg at a recent meeting of the British Psychological Society. Prof. Ginsberg's caution and legitimate scepticism could scarcely be greater than they are. Yet his attitude towards the popular conceptions is sympathetic and constructive. At the present time such an approach is particularly welcome, attempting as it does a reconciliation between the standards of scientific thinking and the demand for positive contributions to an important topical question of wide interest.

Allowing fully for the effects of prejudice in observers and for the difficulties of defining both 'nation' and 'character', Prof. Ginsberg still thinks it a mistake to dismiss the idea of national character as a mere illusion. Instead, he asks in what direction there lies most hope of detecting and identifying differences in national character. With our present techniques for observing group behaviour he sees small likelihood of demonstrating by direct observation that particular traits of personality are more prevalent among one nation than another. The belief, for example, that the Germans are more docile than the English, or the French more articulate, cannot yet be scientifically

confirmed or disproved by the observation of individual behaviour. As a sociologist, Prof. Ginsberg puts more faith in analysing "the psychological basis of the collective achievements of peoples", their institutions and their corporate policies.

The pitfalls in the way of deducing national character from national institutions are not overlooked. In particular, allowance has to be made for the historical background of the institution (and often its geographical background) and for the class structure from which it emerged. This caution would be needed, for example, in estimating the significance for the English national character of our public schools, our non-conformist churches, our traditions of diplomacy. Prof. Ginsberg is of opinion that these and other similar difficulties can be sufficiently allowed for to permit of some valid deductions as to the national character implicit in collective achievements.

In illustration of this viewpoint he suggests that both the empiricism and the individualism which many observers regard as characteristically English can best be seen in our institutions. Individualism is evident "in the spirit of the English law which is a law of the liberty of the individual subject, in the strength of local government and resistance to centralisation, in the stress laid by Puritanism on the autonomy of the individual and in a very widespread and deeply rooted impatience of compulsion and restraint". An extreme form of individualism is also deeply rooted, according to widespread opinion, in the German character.

But there is an important difference between the two peoples in that among the English the individualism is counterpoised by a capacity for spontaneous organization, seen in the number of our voluntary societies, and in the history of the trade unions, the co-operative movement and the friendly societies. With this goes also the capacity for what Madariaga has called "collaboration in opposition", important no less in politics than sport. Among the Germans, on the other hand, individualism shows itself in politics as "a strong tendency to particularism and discord and an incapacity for wider unions except when they come under the influence of dominant leaders". Prof. Ginsberg inclines to the view that it is the Germans' lack of capacity for spontaneous organization which makes them seek unity through authoritarian discipline. "It is clear that, for whatever reasons, the need for authority is deeply rooted in German life and that the relationship of inferior and superior pervades all spheres of activity."

The English empirical tendency can be shown in our legislation and our politics, in both of which "there is a disinclination to formulate general principles, and piece-meal enactments are preferred". English international policy is especially tentative and piecemeal, its consistency over long periods being due to the constant influence of our geographical and economic situation and not to a formulated plan. The lack of deliberated, abstract planning in the growth of the British Empire contrasts with the French, and still more with the German, policy towards colonial possessions. A similar tendency is to be seen in English domestic politics and Church history: "in dealing with the practical problems of life the English mind prefers to proceed tentatively, by trial and error."

In contrast to the English tendency stands the German concern for system and generalization. The systematic regulation of practical public affairs, and painstaking and exact investigation in scientific work, form one aspect of the Germans' effort to maintain a balance against excessive individualism and vague emotionalism. In their intellectual life, however, there is a liking for abstract generalizations which "do not seem to be reached by analysis of sense experience but rather by a sweep of imagination or fantasy". Here their interest in system "is often not rooted in the need for order, not the product of a drive to classify and understand, but rather of an imaginative longing for grandiose architectural schemes".

It goes without saying that these views cannot claim the status of scientific conclusions. They reflect subjective impressions. But as distinct from impressions of transient everyday behaviour, observed under conditions which are seldom defined and never exactly repeatable, these views are interpretations of a body of permanent material —institutions, writings, historical policies—which remains available for further inspection and re-interpretation. No one, and certainly not Prof. Ginsberg, would deny that by the standards of experimental science we are here on most uncertain ground. Yet a consensus of the opinion of observers who differ in nationality but who are examining much the same data can claim a degree of probability which should ensure serious attention and provisional belief.

To explain differences in national character is even more hazardous than to identify them. The view that national character is based on the biologically inherited constitution of a people, the so-called racial theory, has in democratic countries received ample criticism. Prof. Ginsberg ignores, no doubt wisely, the complication which Jung's doctrine of the 'collective unconscious' has introduced into an already confused problem. But he effectively re-states the objections to the main theory. He insists, however, that we should not go to the other extreme of denying to biological

inheritance all significance as a factor in group character. "Unless we are prepared to deny the inheritance of mental characteristics we must regard it as highly probable that just as there are individual differences there are also group differences and that these play their part in shaping the collective life of groups. . . . The inherited constitution must in some sense put a limit to what can be achieved by social organisation." But Prof. Ginsberg has no hesitation in concluding that historical and social conditions play a much greater part than genetic factors in moulding national character. As he says, "it must be remembered that the range of human potentialities is extraordinarily wide and that upon the same hereditary elements very different social structures may be built. There seems no warrant for assuming any such differences between national groups as would amount to an inherited incapacity of any one for the arts and institutions achieved by another."

The immediate practical significance of this conclusion lies in the consequent recognition that national character is, for all its relative stability, capable of enormous changes. Those who might wish to make an end of the German nation on the grounds of its incorrigibility will find no support in Prof. Ginsberg's careful and comprehensive survey of the problem. He takes the view that even if there is "an inherited element in the character of nations of long standing they nevertheless retain considerable powers of adaptation and the limits of these powers cannot be determined with any accuracy from their previous history".

The means by which profound changes in national outlook and character may come about—such, for example, as the abandonment by the Germans of over-emphasis on authoritarian organization—deserve the fullest attention of social scientists. This question did not fall within Prof. Ginsberg's purview, but it is one on which both sociologists and social psychologists should have important matter to contribute. The former have evidence on the workings of the broader social institutions. The latter may be expected to throw light on the importance in this respect of the characteristic structure of the family in different nations. It is in the family that many of our most enduring social attitudes are learnt and certain fundamental social expectations formed. There can be little doubt that the intimate structure of the family, influenced as it always is by the position accorded to women in the world outside the family, is highly relevant to the emergence of a particular social outlook in adult life. Tempted to despair of a changed outlook in some nations, we have to remember that effective changes in such profound emotional dispositions must occur very largely in childhood—certainly with immense difficulty at any other period—and in the history of a nation like Germany there have not been many generations of children who have grown up during periods when the ideals of democratic co-operation had currency among the adult population.

The impossibility of scientific certainty in predicting the trends of development in national character is no good reason for abandoning all attempt at prediction. Where one observer goes completely astray, another, with greater insight and better opportunities of observation, will be far more dependable. At the present time it may well be that the practical judgment of men of affairs is as good a guide as any more scholarly or scientific assessment. In speaking of the Greeks, for example, Prof. Ginsberg thinks that their recent political and military behaviour "would have been predicted by no student of their character". Yet it is worth while to recall that Mr. Churchill (in "The World Crisis: the Aftermath") reports the belief of Mr. Lloyd George shortly after the War of 1914–18 that "The Greeks are the people of the future in the Eastern Mediterranean. . . . Their fighting power is grotesquely underrated by our generals. A greater Greece will be an invaluable advantage to the British Empire. The Greeks by tradition, inclination, and interest are friendly to us; . . . The Greeks have a strong sense of gratitude, and if we are the staunch friends of Greece at the period of her national expansion she will become one of the guarantees by which the intercommunications of the British Empire can be preserved. One day the mouse may gnaw the cords that bind the lion" (p. 391).

Some of the urgent, practical needs of warfare, notably the guidance of propaganda, demand the close study and collation of all that is known and alleged about the characters of the various nations. To a great extent such a study must be *ad hoc*, directed to answering limited questions of perhaps transient importance. For not only the relatively enduring character of a nation, but also its more transient moods and the particular aspects of character which are uppermost at the moment, are vitally important to the propagandist. To the statesman who must handle the broad issues of future policy the enduring features of national character and the trends of its development are equally significant. There can be few more important tasks for the social sciences than to contribute to a full understanding of the character, mood and prevailing interests of the nations among which the War is being fought, and by which an international order must be reconstituted, wherein all nations of the world may be able to advance along the road of civilization in peace and security.

THE BEHAVIOUR OF NATIONS

The Behaviour of Nations
An Essay in the Conduct of National Organisms in the Nutritional Field. By Morley Roberts. Pp. xi+180. (London: J. M. Dent and Sons, Ltd., 1941.) 12*s*. 6*d*. net.

THE author begins with an analogy that biological readers find difficult, namely, that between the State or nation and an organism. Its limitations concerning phases and duration of life, integration of component units, reproduction and external relations reduce its value. If, however, even a partial value be attached to the analogy, then the special parallel the author draws between the State and a low-grade organism becomes valuable, for there must be few who have not reflected that the greatest common measure of a large mass of humanity must be low; and Machiavelli has told us this for centuries in his own grim fashion.

Morley Roberts sets forth for us here in all its nakedness, gaunt and unashamed, the Machiavellian doctrine that society is based on force, that groups of mankind inevitably compete for nutrition—by which he means supplies of all kinds—that phases without war are but interludes, usually preparatory to another struggle. To him, leaders are chiefly those who perceive and express the movements of their time for new or increased supplies. He does not know what is meant by international morality, and decries the romantic conceptions of the Churches and other idealists. This is accordingly a book for idealists to read if they still feel disposed to indulge in that form of escapism which devotes itself to making paper plans for a better world.

In the world as it is, occupation without effective power of defence against organized mechanism is not real possession. Holland, Belgium, Norway, Poland, Yugoslavia, Greece, Italy, even France, were not really the possessors of their territories; they were temporary holders until such time as the great mechanism should descend upon them. Paper treaties professing to give security to the weak are frail; even worse, they are death-traps not seldom used by the great mechanism to gain time that it may do one job at a time, and that thoroughly.

Irritated national organisms which are equipped with mechanical power have not been amenable to moral reproof or to the diplomatic nursing that has come to be known as appeasement. Appease them by concession, and, at once, by the very principle of their being, they start scheming for more. Moral reproof, as in the pitiful case of Italy and Abyssinia in 1936, is equally futile, and still more irritating, a still greater excitant for the have-not organism which can obtain mechanical resources. Machiavelli told the Prince that he must either destroy or make a (subordinate) friend of his adversary; intermediate policies are disastrous.

Morley Roberts thinks history is largely a record of social pathology; even some of the more optimistic of us will go as far as to say it tells us, in the main, what comes of choosing the second, often even the third best.

The book is full of challenging opinions. Norway, Holland, Belgium, France were really destroyed before a gun was fired. Nationalism is a dream that is fading, and men in each nation can be found to co-operate with the enemy and to accept his crusade for a unified Europe, based on what the author calls the tribe, wherein are no differentiations, no parties, for parties would mean differentiation. The collapsed nation States of the west and north-west had advanced dangerously far beyond this tribal stage, and they acted as hypnotized rabbits facing a giant stoat. Nothing that has happened in the last three years but could have been foretold by any German boy of reasonable intelligence between Passau and Heligoland as the inevitable line of action of eighty million claustrophobes, lured, as ever, by the open sea and the sunny south, and pressed on by the spectre of the Slav birth-rate. Long-range politics are in large measure a function of the birth-rate. The author is fond of Spinoza's statement that he wished to understand rather than to abuse a thunderstorm, and the publisher refers to the book's passionless analyses; but, for all that, the fire burns fiercely under a biological cover.

There is another picture to be drawn. Units within which there is some legal restraint, some mutual aid, have grown from the days of hunter-collector groups through those of village cultivators and of rival city States to, and now just beyond, those of tribes and nations. What next? Are we to witness rival giant powers, Atlantic or Anglo-American, European or Germanic, Russian or 'Heartland', in the sense of Mackinder's remarkable forecast in "Democratic Ideals and Reality"; and Oriental? Or can we try, by reducing divergences of standards of living, to achieve a world order with a backing of adequate strength?

H. J. FLEURE.

SCIENCE OF DIETETICS

Hutchison's Food and the Principles of Dietetics
Revised by Prof. V. H. Mottram and Dr. George Graham. Ninth Edition. Pp. xxvii+648. (London: Edward Arnold and Co., 1940.) 21*s*. net.

I THINK some who read this book will have much the same thoughts that flash to mind when, after years, one meets an old friend of boyhood days. Pleasant memories of the past intermingle with instant impressions that his hair is greying and that he has acquired a 'middle-aged spread'.

I first met "Hutchison" nearly thirty years ago when he was a youngster of ten and showing vigorous and sturdy growth. He must have inspired many thousands as well as myself with his youthful enthusiasm for the science of food and nutrition. Then came maturity and well-earned distinction. Now, he is admittedly in early middle age and there appear to be signs that the prime of life is passed. It may be nothing more than a climacteric, because with the ninth edition, and the twenty-third printing "Hutchison" is in the course of becoming "Mottram and Graham". A transition of this character is always rather a critical period in the life of a standard text-book, which it may or may not successfully survive. Some years ago a group of Bayliss's friends—the reviewer was one of them—'revised' his famous book on "General Physiology". The motive was admirable because he was at that time too ill to undertake the revision himself, and his friends and colleagues were happy to show their deep affection for him by taking on a task which he had set his heart on completing. Well-meaning as were our efforts, they were, I think, a failure. The book lost almost all that had formerly reflected the personality of Bayliss himself. Sometimes there is more success, "Kirke" became "Halliburton", "Halliburton" became "McDowall" and, still, after getting on for a century, we have a widely read and 'standard' work.

I feel sure many thousands of "Hutchison's" old friends will sincerely hope that "Mottram and Graham" survive as fortunately, for there is certainly real need for a trustworthy text-book on this subject, particularly at the present time, when knowledge of the composition and function of foods is of such vital importance.

The reader will find in the first five chapters a good general account of current views on the part played by components of food. Of particularly topical interest is the discussion of protein requirements, a subject upon which experts are prone to differ in a rather alarming manner. Few of us realized, I think, how little definite was actually known about the protein requirements of adults until the exigencies of the War brought us face to face with the need for precise estimates. It is one thing for a committee of the League of Nations to sit around a table in peace-time and declare, quite arbitrarily it must be remembered, that 1 gm. per kilo of body weight is the desirable daily intake of protein for any ordinary man or woman. It is a very different story when an estimate is required of the least quantity of protein that must be provided to keep the population in good health under war, or even siege, conditions.

Uncertainty of a no less disturbing nature troubles us when we try to provide for the children, and one cannot but admit a feeling of humiliation when so great a volume of literature on protein reveals so little clean-cut information.

The chapter on vitamins is not the best in this section of the book. It is a little scrappy and could be greatly improved with small effort. For example, the references to the part played by vitamin D in calcification of bones and teeth is particularly disappointing. The reader might easily get a wrong impression from a statement such as that on p. 130 that the members of this group of vitamins act as catalysts at the site of calcification. There should have been a wider treatment of the influence of these vitamins on absorption of bone-forming elements, particularly phosphates, from the gut. Last, but by no means least, there is reference to Mellanby's "toxamin", which has been 'as dead as mutton' since the function of phytic acid in cereals was revealed.

The chapters on the composition of foods provide, as they have always done, a wealth of useful information. They would be even better if subjected to a little judicious pruning here and there, for one still comes across analyses and comments which seem to date from the 'good old days'.

This is a minor criticism but by no means an unimportant one. It may be illustrated by reference to the chapter on wines, which dates, all too obviously, from the days of Thudichum and Dupré's classic work, which, however dear to the heart of a wine-lover, is scarcely to be regarded to-day as a standard work on the composition of wines. The table of analyses on p. 457 is a museum

piece for a Victorian setting, but it strikes no note to-day, except one of sorrow for the passing of the lovely Château d'Issan, a victim of the tragic year 1932.

There are several useful chapters on practical dietetics in health and in sickness. They, too, need a little further careful pruning and grafting here and there to make them as good as one would wish, but they contain a great deal of valuable information. J. C. D

THE USES OF X-RAYS

Applied X-Rays

By Prof. George L. Clark. (International Series in Physics.) Third edition. Pp. xvii+674. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 42*s*.

It was the late Lord Rutherford who reminded us again and again that the advance of knowledge depends upon the development of technique. Alongside this, it is equally certain that the last decade or so has provided a continuous reciprocity between the fascinating task of finding new outlets for applied physics, and the urge to press on still further with instrumentation in order to attack new problems. Probably this dual process is nowhere better seen at work than in the field of X-rays. A bare half-century has in fact sufficed to bring us from that charmingly modest—almost detached—announcement by Roentgen at Würzburg to the present moment, when X-rays are nothing accounted of in everyday life.

A consequence of all this is that to appreciate what X-rays can do constitutes a minor research in itself, since their uses extend to almost every industry, and to medicine, biology and the arts. A case in point is that of non-destructive testing. To control at every step the fabrication of a product is often essential, but may be comparatively easy, since one is not confronted with the complexity and value of the finished article. Obviously, only very special physical methods can cope with this final stage, at which X-rays have proved their worth time and time again. Examples are the examination of golf-balls for correct core-centration, of shells and cartridges for proper filling, the counting of packed materials, including the possibility of locating 'foreign bodies', whether they got there by accident or by design.

Of more purely scientific interest has been the rapid advance in our quest for substances displaying exceptional properties, like the long-chain polymers, and synthetic materials in general. X-rays have been the means whereby the desired characteristics can be explored, and the edifice erected according to the laws of molecular architecture. Strength and resilience, plasticity and flow, are features which are not beyond us to produce at will. Moreover, when the work is done, it may well be a thing of beauty and a joy for ever.

In the third edition of his "Applied X-Rays", Prof. Clark provides a distinguished survey of the whole terrain of X-ray applications. He is careful to devote a considerable portion of his book to a detailed discussion of the tools at command—tubes and high-tension equipment—together with the amount of theory essential for the proper interpretation of results. This portion is decidedly well done; it avoids the common mistake of overloading the text with complexities far in excess of the needs of most readers. There is a somewhat large corpus of semi-classical subjects like X-ray and atomic spectra, which might perhaps have been more curtailed: t is a moot point how necessary these topics are in a volume dedicated essentially to applications.

It is likely that the chapter on radiography will give the reader the greatest satisfaction, for the reason that it brings together a host of matters rarely found in print together. In the section dealing with the arts, there are unfortunately a number of minor inaccuracies; an important point, however, which the author scarcely makes clear, is that the success—or otherwise—of a radiographic investigation of a painting depends largely upon the varying thicknesses of paint traversed, and not upon their chemical composition. Coal-tar pigments, naturally, do not occur in the Old Masters, and yet X-ray results have often proved extremely revealing in such cases. The reason lies in the fact that the visible paint layers are very thin.

A most intriguing subject is that of micro-radiography, in which a small exposed spot is magnified about a hundred times microscopically, or by projection. A plate of illustrations shows the capabilities of the method.

Prof. Clark has produced an admirable guide to the applications of X-rays; his volume is expensive, but there is nothing quite like it in Great Britain. It can be sure of a welcome.

F. IAN G. RAWLINS.

STEREOGRAPHIC PROJECTION

The Stereographic Projection
By F. W. Sohon. Pp. ix+210. (Brooklyn, N.Y.: The Chemical Publishing Co., Inc., 1941.) 4 dollars.

F. W. SOHON, S.J., director of the Seismological Observatory of Georgetown University, has written a very valuable book. This is a method of representing a solid body (usually figures on the surface of a sphere) on a plane, the centre of projection being a point on the surface of a sphere, and the whole sphere being represented once on an infinite plane. The projection has the merit that circles are represented as circles and that angles are retained. The book was not intended by the author to be exhaustive, but it contains a good selection of proofs, some by vector methods, and explicit applications to many problems including some in astronomy, hydrodynamics and seismology.

The seismological problem discussed by Sohon is the determination of the epicentre of an earthquake from a knowledge of its great circle distances from several seismograph stations by the semi-tangent method using geocentric latitudes (compression $\frac{1}{297}$). The degree of accuracy of this method will naturally depend on the accuracy of the seismograph timing, the accuracy of the travel-time tables for the two pulses recognized, and the degree to which the depth of focus may be allowed for in computing the great circle distances.

The book is recommended to students and research workers in mathematics (especially geometry, differential geometry, complex variable and hydrodynamics), cartography, astronomy, seismology and crystallography. It is handy in form, well arranged, printed and produced, contains tables including stereographic projection elements for all seismograph stations computed by Weston-Woodstock students, and there is an adequate index. E. T.

POWER PLANT FOR AIRCRAFT

Aircraft Engines
By A. W. Judge. Vol. 2. Pp. vii+446+93 plates. (London: Chapman and Hall, Ltd., 1941.) 30*s*. net.

THIS is the second volume of what is intended to be a comprehensive treatise on aircraft engines and accessories. The first volume, reviewed in NATURE of February 8 (p. 158), dealt largely with the factors which influence the performance of the engine under varying conditions of operation, but included also descriptive matter relating to carburetters, superchargers and cooling devices. The present volume deals mainly with engine types, details of construction, the remaining accessories, operation and testing.

Steady and rapid improvements in specific output and economy have taken place in recent years, largely due to supercharging, higher compression ratios, the use of light alloys and of high-tension steels. In the twelve years prior to 1940, speed has increased from 1,800 to 2,800 r.p.m., and piston speeds of more than 2,500 ft. per min. are now normal practice. Brake mean effective pressures have also increased from 125 to 220 lb. per sq. in. and more, so that the b.h.p. obtainable from a given cylinder capacity has increased by 150 per cent in this period. There is little doubt that these figures are conservative in relation to still more recent developments, and the author quotes brake mean effective pressures of more than 300 lb. per sq. in. at 2,400 r.p.m. which have been obtained from engines operated by sleeve valves.

In making comparisons between different types of engines, there are a number of important factors to be considered. These include power plant drag, moments of inertia of the engine about axes perpendicular to the axis of rotation, vulnerability to attack in the case of military aircraft, specific fuel consumption, specific weight, reliability under operation at full power for lengthy periods, accessibility for overhauls and adjustments, possible obstruction of view of pilot, convenience of attachment to fuselage, variations of torque reaction, cooling arrangements and silencing. The degree of complication involved will also influence the cost of manufacture and rate of output, in addition to increasing the necessary stock of spare parts. The relative importance of the different items will, of course, depend upon the nature of the duty for which the engine is designed, and this accounts to a large extent for the variations in size and type of the engines in actual use.

The author of the volume under review has borne all of these factors in mind and has presented a considerable amount of information which is not easily available in other than scattered publications, a list of which is given in an appendix, and gives a clearer picture of modern developments, accompanied by diagrams and illustrations which are really informative. Search for information on a particular type of engine or accessory, which is facilitated by an excellent index, seldom fails to supply the required data in a concise but intelligible and useful form.

The development, present position and future possibilities of the compression-ignition engine, both two-stroke and four-stroke, are given adequate discussion and accompanied by descriptions of recent types. There are undoubted possibilities in compression-ignition engines for long-distance flights, particularly where flights at high altitudes are concerned, and in some respects the design problems are simpler than is the case with road vehicles operating at widely varying loads and speeds, so that the information and data given by the author will be welcomed.

Components, lubricating systems, the ignition system and exhaust systems all receive concise but adequate treatment, and in no case does the author descend to mere catalogue particulars.

There are very few misprints, and these are fairly obvious. On p. 225 the author refers twice to the 'Mitchell' thrust bearing, on p. 324 a plug gap of 0·24 in. is mentioned and on p. 372 the Kadenacy effect is referred to as an exhaust pipe effect, which is, of course, not the case.

The publishers have studied the convenience of users by the adoption of a flexible type of binding which permits of the book being left open at any desired page, by the clear reproduction of the numerous diagrams and half-tone illustrations, and the clearness of the type used.

Generally the second volume maintains the high standard of the first volume, and is a very useful and up-to-date contribution to the study of aircraft engines. A. T. J. K.

ELECTROCHEMISTRY IN THE UNITED STATES

Industrial Electrochemistry
By Dr. C. L. Mantell. (Chemical Engineering Series.) Second edition. Pp. x+656. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 38s.

THE first edition of Dr. Mantell's valuable work has been thoroughly revised and brought up to date, and has grown by some 130 pages in the process. The text has been rewritten almost entirely, so much so that it may be asked whether the author has not taken unnecessary trouble in this respect, since quite large portions of the present version are mere paraphrases of the original.

A feature of the book which cannot fail to strike an English reader is that it appears to indicate the United States as the source of nearly every electrochemical discovery and development subsequent to those of the early pioneers. While admitting the great progress made in the United States and the magnitude of its electrochemical industries, it is to be hoped that the importance of maintaining the international character of the best scientific works is not being forgotten. Such a state of affairs has prevailed for some time in certain parts of Europe, where it is probably due to a deliberate national policy. No such accusation is made against the author of the present work, for it is clear that the fault, if such it can be called, is not easily avoidable. The best chapters are evidently compiled from data supplied by men with a thorough practical knowledge of their subject, and it is to this fact that they owe their excellence. Any attempt to apply the same procedure for foreign countries must necessarily be very difficult and, in present circumstances, almost impossible. Rather than present second-rate material, the author has decided to confine his attention to a high-grade, but somewhat restricted, source of supply.

It is suggested that the difficulty might be met in a future edition by largely increasing the number of references to foreign literature and by adding a few more descriptions of European plant when obtainable. Space for this could be saved by omitting much of the theoretical matter, which may be found in any text-book on physical chemistry, the chapter on electronics and most of the appendix; surely a table giving the pounds of xenon deposited by 1,000 ampere hours is not of much practical importance.

Leaving the question of nationalism, which is perhaps a side issue, full support may be given to the author's contention that electrochemical engineering should be regarded as a branch of chemical engineering. Chemical engineering involves not merely a description of plant, but also its efficient operation, and for this purpose data are required. The chapters on electro-plating, electro-refining and electro-winning, which have

been expanded very considerably and, as already mentioned, bear the impress of the expert, are of particular value in this respect. They illustrate also the importance in commercial practice of small traces of impurities and the careful control of conditions, factors which are sometimes neglected by the inexperienced.

The short chapter on power generation and economics, while admirable for its conciseness, might be further expanded with advantage, and the same applies to materials of construction for electrochemical apparatus, which, considering their importance, are treated with undesirable brevity. On the other hand, the first part of the chapter on electrical discharge in gases seems somewhat out of place.

The whole work is profusely illustrated with flow sheets, diagrams and drawings of plant, while the text is clear, carefully arranged and with no suspicion of dullness. In short, this member of the Chemical Engineering Series is fully up to the high standard of its predecessors and in some respects is in advance.

H. E. WATSON.

REPTILES OF CEYLON

The Tetrapod Reptiles of Ceylon
Vol. 1: Testudinates and Crocodilians. By P. E. P. Deraniyagala. (Colombo Museum Natural History Series.) Pp. xxxii + 412 + 24 plates. (Colombo: Colombo Museum; London: Dulau and Co., Ltd., 1939.) 10 rupees; 15*s*.

MUSEUMS of natural history exist in order that they may make collections, and by the development of systematic zoology and botany, and of similar aspects of mineralogy and geology, so organize them that they are available to scientific workers. Their own publications have therefore been concerned primarily with taxonomy, taking the form of systematic catalogues. But recently, when old-fashioned 'systematics' have reached a point at which further exploitation has given diminishing returns, the interest of museum staffs has spread into wider fields, and such portents as the establishment of a department of experimental zoology, with an exceptionally well-equipped laboratory, by the American Museum of Natural History, have made their appearance.

Thus the publication by the Colombo Museum of a "Monograph of the Tetrapod Reptiles of Ceylon", which in 412 pages discusses only ten species of Chelonia and Crocodilia, is less surprising than it would have been ten or twenty years ago.

In this most interesting work, the author, Mr. P. E. P. Deraniyagala, gives very full and excellent taxonomic descriptions of these species, which are founded on abundant materials and include valuable quantitative accounts of the range of variation within each species. But he adds to this expected information an immense mass of 'natural history'. His own work in the field and the laboratory, combined with facts drawn from the experiences of commercial fishermen and country dwellers, has enabled him to record the life-history of these reptiles, their nesting habits, the time of incubation, the behaviour of the young, their rate of growth, the feeding habits of the adult and indeed to enable us to see them as living animals pursuing their daily lives in the seas and lands of Ceylon.

Such information has very seldom been brought together in a collected form, and is most useful to anyone who, as a palæontologist or otherwise, has to consider the possible habits of animals, so far as they may be deduced from their structures.

In addition to this mass of new knowledge, the author gives us more. He has fetched into the laboratory, or rather into the garden, the eggs of some of these reptiles and has followed the course of the development of their external features in stages of a known age of incubation. The most important and interesting form with which he has worked is Dermochelys, the leathery turtle, an animal which differs so much from all other living Chelonia in the structure of its shell that it has necessarily taken a leading place in all discussions of Chelonian phylogeny. Mr. Deraniyagala not only collected the eggs of this animal and hatched them artificially, but also was able to rear the young, and indeed keep an individual until it was accidentally killed when nearly two years old. He has thus been enabled to give much new and most interesting information about the whole course of development, including that of the shell.

The monograph includes similar, though usually less complete accounts of the development of other forms, and for many of them gives an account of the development of the bones of the head, especially of those relatively late stages which have so seldom been considered, but which often present facts of much interest.

The whole is richly illustrated by the author's own often very vivid drawings and by photographs, and reflects great credit, not only on the author, but also on the Museum of which he is the director.

D. M. S. WATSON.

THE ORIGIN OF LIFE*

BY DR. C. F. A. PANTIN, F.R.S.
DEPARTMENT OF ZOOLOGY, UNIVERSITY OF CAMBRIDGE

UNTIL one hundred years ago the origin of living organisms was not a major problem in biology. Apart from the biblical creation, the view was frequently held that many at least of the simpler organisms were produced by spontaneous generation. The ease with which this idea was accepted was partly due to imperfect observation and partly to the view that there was a completely graded sequence between the living and the non-living. This found its most complete expression in the detailed 'scale of beings' of the eighteenth century. The disproof of individual cases of abiogenesis did not change this attitude until Pasteur showed that every supposed case of spontaneous generation was, in fact, due to infection by living organisms.

Pasteur's work raised the question of how the first organisms came into being. The publication of the "Origin of Species" made this one of the fundamental questions of biology. It is certain that at one time life, as we know it, could not have existed on earth. It must, therefore, either have arisen spontaneously from lifeless matter or have been conveyed to the earth from elsewhere after it had become inhabitable. The theory that life originated by infection from without has been discussed by Arrhenius and others. Bacterial spores may be conveyed to outer space by being carried to the upper atmosphere and then repelled from the earth by virtue of their electrical charge. Arrhenius showed that light pressure could then distribute such spores throughout the universe at an astonishingly high speed. In this way it would be possible to spread life from planet to planet. But apart from the fact that this hypothesis only shelves the question of how life began, it is rendered impossible by the physical conditions to which any living organism must be exposed in outer space. Spores might survive intense cold or a fair degree of heat. But they could not withstand the intense short-wave radiation from which we are shielded by the oxygen of our atmosphere. A minute spore can have no protection against this radiation, for the individual molecules of which it is composed will be destroyed.

We are thus forced to suppose that life began on this earth, and Pasteur's experiments must be taken to mean that life can only begin under very special conditions and that such special conditions must be sought for in the geological past. We can therefore ask three questions: What were the first organisms like? When did they arise? Under what conditions did they arise?

Evolution has carried life from simple to more complex organisms. Side by side with the complex existing organisms we find others which are far simpler. It was supposed that among these we might find more or less unchanged survivals of the primitive living organisms of an earlier age. There is much to be said for this view, though it involves a very important assumption. Evolutionary trees were made and still are made which are based upon it. Haeckel constructed a phylogeny based on existing organisms. An amœba was not only an existing organism, but its grade of organization also corresponded to that of an actual ancestor. More primitive than amœba was Haeckel's 'monera', structureless protoplasm supposedly without a nucleus. Existing monera disappeared in the light of investigation, but the idea of a 'primordial slime' remained.

'Primordial slime' was an invention of zoologists. It was, therefore, an animal. But animals require food, and their normal food can be traced to plants. Ray Lankester tried to evade this difficulty by supposing that original organisms "fed upon the antecedent products of its own evolution". One must, however, explain the presence of 'albuminoids' in a suitable form for animal consumption, and also how the animals obtained oxygen for respiration. There is good reason for supposing that all our oxygen was produced by plants; and the physical and chemical requirements of plants for growth are far simpler than those of animals. Church supposed that the first organism was a planktonic flagellate producing its substance by photosynthesis.

It is difficult to suppose that an organism so complex as a flagellate could arise by the spontaneous aggregation of its parts from non-living material. Even the smallest flagellate must contain about 10^{10} organic molecules. But is the aggregation of matter into a simple organism so improbable as it seems? May their morphological complexity be a natural property like the complexity of crystal structures? Leduc reproduced some of the obvious features of living organisms by inorganic models such as osmotic growths in silicate solutions. But the correspondence between these models and living organisms was very incomplete, and unquestionably the structure of a flagellate is

* Substance of a lecture delivered at the Royal Institution on May 27.

far too complex for us to suppose that it has arisen spontaneously. Nor is there any need for us to suppose this, because there exist much simpler organisms than flagellates.

The smallest known living organisms are the bacteria. These grade into the yet smaller viruses. It is a question of definition whether the latter are considered as living or not. Bacteria are of far simpler organization than flagellates. They are still, however, sufficiently complex to make it difficult to suppose that any bacterium could ever have come into being by the chance aggregation of material. They are saprophytes and require complex organic media which they make use of in very varied ways. Many are anærobic. In the viruses we have still smaller units than bacteria. Their properties as infective agents resemble those of pathogenic bacteria. They possess properties which are associated both with living and non-living systems. Their power of growth and reproduction is a characteristic feature of living organisms. At the same time their extremely small size overlaps the size of large molecules, and they have been obtained in the crystalline state. It seems scarcely possible to make this property agree with our normal ideas of the structure of living matter. Instead of a complex arrangement of different kinds of molecules on a small scale, it seems that some viruses simply consist of nucleo-protein molecules. Whether the virus particle is living or not, it is always associated with living tissue, though we may yet find a non-living medium suited to its requirements.

Our search for the simplest type of existing organism leads us into a rather curious position. We can find bacteria of smaller and smaller size, and still smaller things, the viruses. Whatever view is taken of the nature of the virus, it certainly makes conceivable the existence of living material on an almost molecular scale. From the point of view of finding the simplest organism, this is certainly a great step forward. But from the point of view of conceiving of the first living organism, what has been 'gained on the swings seems to have been lost on the roundabouts'. Compared with plants the chemical environment required by bacteria is very complex and varied. It may even require the absence of oxygen. Viruses even seem to require living tissue itself for their existence. While it is easier to suppose that these minute forms might arise spontaneously, we can only suppose their existence in an environment which is very different from, and much more complicated than, that which exists to-day. The origin of a suitable environment becomes as much a problem as the origin of the organism.

When and under what conditions did life arise ? It is still one of the remarkable facts of palæontology that the fossil record suddenly fails below the beginning of Cambrian times. Unequivocal remains of Pre-Cambrian organisms are few, and none are easy to interpret. Yet the abundant fauna of the Cambrian itself already shows all the main groups of animals, so that there must have been a long period of evolution before this time. Though poor in fossils, Pre-Cambrian rocks offer important information. The oldest rocks dated by radioactive methods are some 1,700 million years old. Before that there is evidence of sedimentary rocks which it has been suggested carry us back to 2,000 million years. Radioactive study of the age of meteorites leads us to conclude that the age of the solar system is not greater than 2,800 million years. Estimates by other methods agree with this. We can therefore examine rocks which cover a substantial portion of the earth history. The occurrence of graphite in the Pre-Cambrian is of particular interest because it suggests the early existence of organic matter and possibly of life. Most of the evidence of the earliest rocks suggests that conditions on the Earth's surface did not differ substantially from those of the present day. The existence of very old sedimentary rocks indicates the existence of exposed land and familiar weather conditions. There is some reason for supposing that the sea has not altered fundamentally in its composition since very early times. The Earth probably only took a matter of thousands of years to cool to approximately its present temperature ; and there appear to have been Pre-Cambrian ice-ages. Whatever factors control the temperature on the earth, they appear to have operated for a very long time.

There is, however, evidence of one important change in the course of Pre-Cambrian times. These ancient rocks have been exposed to great changes, but there is some reason for supposing that before the middle Pre-Cambrian iron was laid down in them in the ferrous form, and not until after this time was it laid down in the fully oxidized ferric form. This is important because it suggests a lack of oxygen in lower Pre-Cambrian times. The idea that the early atmosphere lacked oxygen is an old one. The present oxygen content of the atmosphere certainly depends on plants. Photosynthesis by marine planktonic diatoms alone produces oxygen at a rate which would regenerate the whole oxygen of the air in about 100,000 years—a geologically negligible period. Photosynthesis by plants may have become an important factor in middle Pre-Cambrian times. Before that an atmosphere of carbon dioxide such as that which occurs upon Venus probably predominated on the earth. The geological record thus suggests the existence of organic matter at a

very early period, under physical conditions not wholly different from those of the present day, except that there may have been a change from anærobic to aerobic conditions during the Pre-Cambrian.

The early presence of an anærobic organic medium finds support from another quarter. We know now that the larger planets have developed enormous atmospheres of hydrocarbons and ammonia from the solar material of which they are composed. The overwhelming reducing character of this material thus leads to the development on a planet of an anærobic organic medium. In a planet such as Venus, there has been further atmospheric evolution through the inability of the gravitational field to retain hydrogen, so that carbon dioxide has been produced. Venus and the Earth are very close in size. A similar condition must once have prevailed on the Earth, and would rapidly do so again if photosynthesis ceased. The reducing character of planetary material leaves no place for free oxygen except through the intervention of photosynthesis or some analogous process.

We do not know how complex would be the organic molecules formed in the original medium. Molecules of kinds utilizable by bacteria would fairly certainly be produced. We have seen that still simpler organisms require a still more complex organic environment, the nature of which we do not yet know. It helps us little to point out in our ignorance that an original planetary organic medium might develop the required environment. But one thing seems certain, an organic environment developed in physical equilibrium on a planet could not of itself develop living organisms. For one of the characteristics of life is that its existence requires a supply of energy, either as radiation or as substances at a higher chemical potential than their surroundings. A system in equilibrium cannot provide this; but solar radiation might have done so, at least before the atmosphere developed oxygen and absorbed its most active components.

The answer to the question "How did life originate?" thus seems to depend on the question "What are the environmental requirements of simple bodies such as the viruses, and could these requirements have been met in the original organic environment?" The answer to these questions will carry with it the answer to many other fundamental questions in biology.

THE SEARCH FOR ECONOMIC PLANTS*

By ARTHUR W. HILL, K.C.M.G., F.R.S.

DIRECTOR, ROYAL BOTANIC GARDENS, KEW

THE history of the spice plants has been dealt with at some length since they have played so important a part in geographical discovery, territorial acquisitions, and wars between European nations. There are however several plants of great economic importance which have travelled far from their lands of origin, of the wanderings of which we have no certain records. Among these are the coco-nut, sugar cane, banana, cassava, ground nut, and possibly the West African oil palm.

The coco-nut has no doubt been transported partly by ocean currents and partly by natives voyaging from island to island in the remote past when they took the nuts with them for food and planted them in the islands or coastal regions to which they migrated. Of ocean transport we have recent evidence in the germination of coconuts washed up on Anak Krakatau IV in 1932. The original home of the coco-nut seems definitely to have been the East Indian Islands, whence it has travelled to the West Indies and to America.

* *Continued from p.* 16.

Sugar cane, also East Indian, must have been similarly conveyed by natives for food on their voyages and then planted by the settlers in their new homes. In this way it has been distributed throughout the tropics before the existence of historical records. The edible banana, probably native in Thailand and Malaya, must also have been transported in much the same way.

Both the ground nut (*Arachis hypogea*) and the oil palm (*Elœis guineensis*) afford puzzling problems. The ground nut is now the staple product of The Gambia, but all its near allies are natives of Brazil and there is none in Africa. Similarly, the closely related species of Elœis occur in Brazil, but there is an allied species in Madagascar. It is an open question whether either economic plant is truly native in West Africa; if not, then it seems probable that natives voyaging from Brazil to West Africa may have brought over both the ground nut and oil palm, and also the American cassava (*Manihot utilissima*), as food in their

vessels, and so they became established on the west coast of Africa.

The cashew nut (*Anacardium occidentale*), much used in confectionery and like salted almonds and pine kernels on our dinner tables, which is a native of tropical South America, was introduced into South India in early days probably by the Portuguese. South India now supplies the major part of the world demand, and particularly the large markets of the United States of America. Nearly all the nuts imported to Great Britain and to the United States come from the south-west coast of India. Cheapness in the preparation of the product is the main reason for this somewhat anomalous condition of affairs.

Two misconceptions as to the original homes of economic plants may be mentioned here. First, the Jerusalem artichoke had nothing to do with the Holy Land—the name Jerusalem probably being a corruption of Terneusen in Holland, as Sir David Prain has ingeniously suggested, where tubers were first landed when they were brought over from America. Nor were either the New World pine-apple or prickly pear to be found in the Garden of Eden as figured by Parkinson on the title-page of his "Paradisus".

Coming to more recent times, one is reminded of the attempt by Captain Bligh in the ill-fated voyage of the *Bounty* to introduce the bread fruit (Artocarpus) from Tahiti to the West Indies, and of the success of his efforts on his second voyage, and of the introductions of economic plants and also, alas, of weeds to Australia and New Zealand as impurities in the seeds of the imported crop plants.

A brief reference must be made to the introduction of Cinchona and Para rubber from South America to Kew, and thence to India, Jamaica, Ceylon and Malaya, in 1861 and 1876 respectively. Flourishing plantations of Cinchona exist in the Nilghiri Hills and at Mungpoo and Munsong near Darjeeling, but those in Jamaica have not been maintained. Attempts are now being made to extend the cultivation in East Africa and also in Panama and Porto Rico. Java, however, is the chief source of the drug, mainly because the climate of the island is particularly favourable for the cultivation of the species which yield the greatest amount of quinine. Java, unlike India, has two rainy seasons, the south-west and north-east monsoons, which produce conditions very like those which occur in the Andes. The soil also is very favourable, but Java's success with *Cinchona Calisaya* types is mainly due to climate. Java has also been fortunate in obtaining seed of a high-yielding form of *C. Calisaya*—*C. Ledgeriana*—which has flourished under Javan conditions.

After the stocks of *C. succirubra* and *C. Calisaya* had reached India, Mr. Charles Ledger, who had obtained seed of a high-yielding form of *C. Calisaya* collected near Pelechuco, to the east of Lake Titicaca, offered this seed to the superintendent of the Government Cinchona Plantations at Ootacamund, who rejected it. He then offered it to the Dutch, who had been experimenting, somewhat unsuccessfully, with Cinchona in Java. The Dutch bought the seed, and so came about the flourishing industry in the island.

One of the assistants in the Nilghiris, however, a gardener from Kew, extracted some of Ledger's seed, and sowed half of it in the Nilghiris and sent the other half to Mungpoo. When the superintendent saw the seedlings and learnt their origin he had them all thrown away. Those at Mungpoo, however, were under the care of Mr. Gammie, who appreciated their value and kept them; they proved to be as valuable as had been stated by Ledger. This form and other good-yielding strains of *C. Calisaya* are still in cultivation at Mungpoo and Munsong. In any event, as it has since been found, *C. Calisaya* and its forms do not succeed under the conditions in the Nilghiris, nor do they thrive quite as well in northern India as they do in the better climatic conditions of Java.

More recently Kew has taken an active part in the growing and distribution of species of Hydnocarpus (Flacourtiaceæ), native in Burma, Indo-China and the East Indies, the seeds of which yield chaulmoogra oil, a specific for leprosy. With regard to this product it is interesting to mention that the resident physician of an asylum at Bangkok was treating the lepers there and trying to get chaulmoogra oil for the purpose when a botanist visiting the hospital was able to point out that supplies were close at hand: a tree was actually growing in the hospital compound, and it grows plentifully in Thailand.

Seeds of Aleurites (Euphorbiaceæ), the source of the Chinese tung oil, a high-class drying oil used for paint and varnish, have also recently been distributed by Kew to suitable parts of the Empire.

The recent widespread introduction of plants of economic importance to the tropical possessions of Great Britain and other countries has opened up political, as well as botanical, problems of considerable difficulty.

The growing of the West African oil palm in the Dutch East Indies, where they have been fortunate in establishing a pure-breeding type of good quality oil palm, is a case in point which may set up a state of economic warfare, as also the establishment of the clove industry in Madagascar and cocoa in West Africa versus Trinidad. The effect of the sugar beet subsidy on sugar-cane

cultivation in the West Indies, the competition of sisal in East Africa with the native product from Mexico, and the plantations of uniform varieties of New Zealand flax in the Argentine afford further examples where economic botany and policy may conflict.

Then again, the ease of transport and the cultivation of economic plants under plantation conditions disclose serious botanical problems. Not only may insidious diseases be easily transported by air, but also large areas of crops grown under plantation conditions afford a very ready means for the spread of any insect or fungus disease. Among the diseases which now threaten important economic products may be mentioned the Panama and the leaf spot diseases of bananas, Cacao witchbroom of cocoa, mosaic of cassava and other economic crops, wither tip of limes and cloves in particular. Such maladies necessitate researches in order to try to produce forms and varieties which may be immune to the diseases, and research in this direction is being undertaken especially by the Imperial College of Tropical Agriculture in Trinidad (see NATURE, March 8, p. 282; March 15, p. 313; March 22, p. 344; March 29, p. 380) and the East African Research Station, Amani, as well as by specialist officers in the Departments of Agriculture in the Dominions, Colonies, and in India. Attempts are also being made to discover higher-yielding forms of such economic plants as sugar cane, rice, para rubber and cacao, by cross-breeding and selection, and when found, propagating them by budding and grafting, cuttings or seed.

With regard to bananas, research is being undertaken to find wild types of Musa in the original home of the edible banana, in the hope of finding types immune to Panama disease, which can be used for cross-fertilizing with cultivated forms; similar work is also being undertaken in Trinidad with regard to Cacao. As we have recently found at Kew that young shoots of Cacao strike fairly rapidly, it will be possible to take cuttings from pure races of high-yielding plants, and so save the labour of budding and grafting.

Other economic plants which are receiving the attention of Kew at the present time for the benefit of our tropical possessions include passion fruit, papaw, cassava, Ephedra, Derris and tuba root or barbasco. The first three mentioned are affected by virus diseases and various types have been sent out to Amani in order that forms resistant to the virus disease may be raised in East Africa. Ephedra, Derris and tuba root yield important insecticides, and attempts are being made to cultivate plants yielding the highest quantity of rotenone, which is very variable in different strains and species. Stocks obtained at Kew have been sent to the West Indies in the hope that a profitable industry may be established to meet the demand.

It may be useful to summarize, in conclusion, some of the more important economic plants which now form the principal industries of the countries to which they have been introduced.

Cacao, which is native of South and Central America, has been introduced to Trinidad and other West Indian islands and has for many years been one of their staple crops. More recently it has been introduced to the Gold Coast and is now the mainstay of that Colony.

Cinchona, also from South America, has been of great benefit to India and to Java.

Para Rubber (*Hevea*), which was brought from South America, is now an important source of revenue to Malaya.

Sisal (*Agave*), native of Central America, is now extensively planted in Kenya and Tanganyika and is a staple product in East Africa.

Cloves from the Spice Islands are the chief product of Zanzibar and Pemba.

Cotton has been introduced to various parts of the Empire, and is now a very important source of revenue to the Sudan, Uganda, Nigeria, etc.

The introduction of *Tea* from China to Ceylon and India has transformed vast areas of these countries and is a very important source of their revenue, while the introduction of *Coffee* to Jamaica and Costa Rica has resulted in important economic developments in those countries.

Reference may also be made to the introduction of *Wheat* to Canada and Australia, which has added so largely to the prosperity of these Dominions. Nor should we forget what the introduction of the *Potato* from South America, and the American *Tomato* has meant in the way of valuable foodstuffs and financial benefit to the growers of these plants in Great Britain and Eire, on the Continent of Europe and elsewhere.

Then, as one further example, there is the great bulb industry of Holland, where the growing of hyacinths and tulips especially, natives of the near East, has brought so much wealth to the country.

The problems raised by the introduction of economic plants from one country to another and their cultivation under plantation conditions provide ample occupation—apart from political considerations which may arise—for the plant pathologist, physiologist, agricultural chemist, the geneticist and systematic botanist. As the writer of the book Ecclesiasticus has so truly said, "When a man thinketh he hath finished, then he is but at the beginning, and when he ceaseth, then shall he be in perplexity".

OBITUARIES

Sir D'Arcy Power, K.B.E.

SIR D'ARCY POWER, who died on May 18, at the age of eighty-five, was first and foremost a writer. This was his finest asset. He gave evidence of this talent early in life, for when he was at the Merchant Taylors' School he won the Tyler Prize for history, and about the same time the prize for the boy best suited for a merchant's office. From that time almost to his death he wrote, and when at the age of seventy-five his works were collected in a complimentary volume, the items numbered more than six hundred.

He wrote on many subjects, though mostly in relation to his own profession. He wrote on the craft of surgery, on the history of medicine, biographies of past surgeons, and of such interesting details as the eyesight of Samuel Pepys and the reason why he discontinued his Diary, and how and when 'Surgeons' became 'Gentlemen'. He had a pretty pen and a happy phrasing, which make what he wrote a pleasure to read. He will be remembered by his writings long after more fashionable surgeons have been forgotten.

At St. Bartholomew's Hospital Sir D'Arcy became surgeon and consulting surgeon. At the Royal College of Surgeons he occupied successively all the more important posts. He was Hunterian lecturer, Hunterian orator, Vicary lecturer, and finally vice-president, as his father, Henry Power, was before him. But his activities did not cease there: he was an authority on Harvey and Hunter, a member of innumerable hospital and benevolent associations, a member of dining clubs and antiquarian societies, and a collector of books. The catalogue of the sale of his books at Sotheby's in the near future is an indication of his wide interests and catholic tastes. His circle of friends, both in Great Britain and abroad, especially in the United States, was immense; and he had a large post from all quarters requesting his help in all matters relating to medical historical research.

In his later years Sir D'Arcy occupied himself congenially and usefully as honorary librarian at the Royal College of Surgeons, there he compiled notices of the lives of the fellows, He was also archivist at St. Bartholomew's Hospital, where he was working on an incomparable set of deeds and documents dating back to the twelfth century, which have so far escaped fire and damage.

In his personal disposition D'Arcy Power was happy. He was full of cheeriness, so much so that students, often apt to discern, dubbed him "Sunny Jim", a nickname that stuck. Though he has now gone, and we miss him, we need have no regrets; for his life was pleasing and all our memories of him are pleasant. He was getting very tired, and was glad to lay down his pack. His seed, too, lives after him; for he leaves a son, D'Arcy, who holds a distinguished position in the medical service of the Royal Air Force; his grandson, D'Arcy Tertius, has entered the medical profession, and his granddaughter holds a commission in His Majesty's Forces.

G. E. Gask.

Mr. John Crompton, O.B.E.

Mr. John Crompton, president in 1937–38 of the Textile Institute, Manchester, died on May 31 at the age of seventy-eight. We are indebted to the *Textile Journal* for the following particulars. He was of the family that numbered one of the fathers of the cotton industry, namely, Samuel Crompton, the inventor of the cotton spinning mule. His father was a hand-loom weaver of silk fabrics, who eventually found his way into a cotton mill in Walkden, where his son joined him at a later date. It was from his father that John Crompton had his first lessons in cloth structure —a subject in which he perfected his knowledge at a later date by means of a model loom he devised. His studentship meant long and arduous study, but his tenacity of purpose and keen application overcame the many difficulties. He was one of the pioneers of technical education, first as a student and then as a teacher; eventually he became an examiner in his subject for the City and Guilds of London Institute.

Mr. Crompton contributed many articles to the technical trade press at a time when textile literature was very scanty. No doubt it was his appreciation of the lack of reliable information that caused him to welcome the advent of the Textile Institute, for which he did much useful work as a member of council for many years and of several of the Institute's committees. In 1930 he was awarded the Textile Institute Medal. He established in memory of his son, Lieut. Harry Dent Crompton, who was killed in the War of 1914–18, the Crompton Prize Fund for textile design. In 1923 the University of Manchester conferred on him the degree of M.Sc. in recognition of his work for the advancement of textile technology.

We regret to announce the following deaths:

Sir Francis Anderson, emeritus professor of philosophy in the University of Sydney, aged eighty-two.

Prof. A. C. Carson, of the Department of Geology, Mineralogy and Geography in the University of South Carolina, Columbia, distinguished for his contributions to seismology.

Dr. G. van Dijk, of the Royal Meteorological Institute of the Netherlands, noted for his work in seismology, on December 19.

Mr. G. R. Redgrave, formerly inspector of schools under the old Department of Science and Art, and later chief senior inspector of technical schools at the Board of Education, on June 14, aged ninety-seven.

Prof. J. E. Taylor, emeritus professor of thermodynamics in Cornell University, on May 4, aged seventy-six.

Dr. Eric Therkelson, head of the Department of Mechanical Engineering of Montana State College at Bozeman, and Collaborator in Seismology for the United States Coast and Geodetic Survey.

NEWS AND VIEWS

Sir Arthur Evans, F.R.S.

SIR ARTHUR EVANS, the well-known archæologist, celebrated his ninetieth birthday on July 8. He has been honorary keeper of the Ashmolean Museum since 1890, having been keeper during 1884–1908. Sir Arthur is undoubtedly the leading British authority in the classical archæological studies, for which he was awarded the Copley Medal of the Royal Society in 1936. In his earlier years he made important contributions to the science of numismatics. His researches in Crete from 1893 onwards resulted in the discovery of the remains of a civilization which he named Minoan after the sea-king, Minos. He traced the Minoan civilization from approximately 3200 to 1400 B.C. His work, "The Palace of Minos", published in six volumes, revolutionized our knowledge of the ancient history of the Near East.

On the occasion of Sir Arthur's ninetieth birthday, Prof. J. L. Myres and Prof. R. M. Dawkins, both former presidents of the Society for the Promotion of Hellenic Studies, presented him on behalf of the Society with an illuminated address. Prof. Myres also presented an address from the British School of Archæology in Athens, of which Sir Arthur was one of the founders and to which he presented some years ago the site of the Palace of Knossos and his property in Crete to be a centre for Cretan studies. Sir Arthur was president of the British Association during 1916–19 and of the Society of Antiquaries during 1914–19. He has been the recipient of many honours from British and foreign universities and societies. All readers of NATURE will doubtless wish to be associated with our congratulations to a scientific worker whose contributions to archæology and anthropology have been of such outstanding importance.

University of London: Air Raid Damage

SOME brief notes on damage done during air raids to buildings of the University of London have already appeared in NATURE (December 21, 1940, p. 802). Information has now been made available of further damage:

UNIVERSITY COLLEGE. Extensive additional damage. The libraries south of the Dome have been burnt out, and also the Exhibition Room, the General Office, the Provost's and Secretary's Rooms, the Council Room, the Botanical Theatre and the whole of the Mathematical Department above it.

KING'S COLLEGE. Damage from blast, fairly extensive in area, and a rough estimate for full repairs is £10,000.

KING'S COLLEGE OF HOUSEHOLD AND SOCIAL SCIENCE. Fairly extensive damage was done when a German bomber crashed on the College.

BEDFORD COLLEGE. Severe damage both by high explosive and incendiary bombs, to the administrative block, the Biological Science block and the Dining Hall. There is slight damage by blast to other parts of the buildings.

QUEEN MARY COLLEGE. Damage by blast in various parts of the building. The West Lodge in the forecourt had a direct hit and was demolished. A rough estimate of the cost of repairs of damage suffered is £5,000.

BIRKBECK COLLEGE. On the occasion of one attack, a small fire was started in the Department of Chemistry, but was brought under control. During one of the fire attacks on London, fires broke out in the surrounding buildings, but the main building of the College escaped; 90 per cent of the College library has been destroyed.

SCHOOL OF ORIENTAL AND AFRICAN STUDIES. Slight damage, mostly by blast, to new (unfinished) building.

MEDICAL SCHOOLS. *St. Bartholomew's Hospital Medical College:* The chemistry block, the old medical school buildings in Giltspur Street, the physiological block, including the library, students' common room, theatre and Pharmacology Department, have been completely burnt out. *St. George's Hospital Medical School:* Roofs of the large lecture theatre and library damaged, and a number of books destroyed. *London School of Hygiene and Tropical Medicine:* The eastern frontage has been completely wrecked: Minor damage by high explosive and incendiary bombs, and by blast, has also been done at St. Thomas's, Westminster, Middlesex, Charing Cross, University College and King's College Hospital Medical Schools, while the London School of Medicine for Women has lost £3,000 worth of furniture and equipment stored in Messrs. Thomas Wallis's depositories.

Social Reconstruction Survey

MR. GREENWOOD, Minister without Portfolio, has announced in the House of Commons that the Committee of the Social Reconstruction Survey consists of the following members appointed by the committee of Nuffield College:—Mr. G. D. H. Cole, reader in economics in the University of Oxford (chairman), the Master of Balliol, the Principal of Lady Margaret Hall, Prof. A. G. B. Fisher, Prof. D. H. Macgregor, Price professor of international economics of the Royal Institute of International Affairs, Prof. A. L. Bowley, emeritus professor of statistics in the University of London; Mr. R. C. K. Ensor, senior research fellow of Corpus Christi College, Oxford; Miss A. Headlam-Morley, and Mr. C. H. Wilson. The committee of the Survey has co-opted Dr. C. S. Orwin, director of the Agricultural Economics Research Institute; Miss Margery Perham, reader in colonial administration in the University of Oxford; Mr. G. Montagu Harris, research lecturer in public administration in the University of Oxford; and Prof. Patrick Abercrombie, professor of town planning in the Bartlett School of Architecture, University College, London.

The terms of reference of the Survey are, briefly to inquire into the rĕdistribution of industry and

population brought about by the War, and the extent to which this redistribution was likely to persist in the post-war period; into the effects of war conditions on the working of public social services (other than the hospital service); into the changes in conditions of living due to evacuation and similar measures taken to meet the war situation, and into the bearing of all these factors on the general problem of national re-organization after the War. The bulk of the expenses of the survey during the current financial year will be borne by the independent resources of Nuffield College, but the Government has undertaken to make a grant not exceeding £5,000 towards the expenses of the Survey in that year.

Provision of Fine Chemicals

Reference has already been made to the scheme inaugurated by the Advisory Research Council of the Chemical Society to facilitate the supply of fine chemicals needed for work of national importance, but which are not available commercially. The sub-committee organizing this work particularly desires to direct the attention of all users of fine chemicals to the existence of this scheme, in order that the greatest possible use may be made of the generous offers of help which have been received from numerous chemists in universities, technical colleges and schools, who have suitable laboratory facilities at their disposal. The scheme, which works in close collaboration with the Association of British Chemical Manufacturers, is an attempt to use to the best possible advantage both the laboratory facilities and the skilled man-power in teaching institutions and other laboratories which may not at present be fully harnessed to the war effort.

Before a substance can be accepted for preparation under this scheme, the Committee must be satisfied that the chemical is unobtainable from any British manufacturing firm and that it is required for urgent work of national importance within the British Empire. The scheme provides for the manufacture of approved items at basic charges which represent only the cost of raw material and such overheads as gas, electricity, etc. There is no charge for the chemist's services. Inquiries from both individuals and firms for chemicals which might be produced under the scheme should be made to the Secretary, Mr. S. E. Carr, Chemical Society, Burlington House, Piccadilly, London, W.1.

War and Industry in India

Comments on the relation of industry in India to the country's war effort are made in an article by J. C. Ghosh in the February issue of *Current Science*. Mr. Ghosh believes that Indian nationalists have a genuine grievance against the Government for lack of vision in dealing with industrial development. During the War of 1914–18, much encouragement was given to many new industries, and, in the post-war years, it was withdrawn on the grounds that only those industries likely to become independent of State support should be supported. Thus the industries commanding an abundant supply of raw material and a ready market for finished products, such as cotton, paper and cement, have gone ahead; unfortunately, this gain has been offset by decreasing prices and shrinking foreign markets for agricultural products. Mr. Ghosh's remedy for this state of affairs—and he thinks it is also a means of assisting defence measures—is to establish as key industries those which are included under the broad heading of metallurgical, engineering and machine tools, chemical and transportation industries.

Mr. Ghosh then discusses what has already been done in these fields. The Tata concern has been responsible for large developments in the iron and steel industry, and it is claimed that India could supply all the steel requirements of the countries represented at the Eastern Group Conference. Non-ferrous industries are not so advanced, but a plant for the production of aluminium with a capacity of 5,000 tons a year is being erected. Engineering is also backward. The heavy chemical industries are developing and may soon satisfy a large part of the country's requirements, but the dye-stuff and fine chemical industry is not satisfactory. The production in India is also urged of locomotives, ocean-going vessels and aeroplanes. It is stated that Indian industrialists fear that the manufacture of motor-vehicles is too difficult to be undertaken by Indian workmen in the near future, forgetting that "the thought and skill required in manufacture have been transferred from workmen to automatic machines". Non-official opinion in India is said, however, to be strongly in favour of starting such industries, and maintaining them as a part of the defence programme of the country.

Health of the Army in India

According to the annual report for 1939 on the health of the Army in India, there were no serious epidemics during the year among British or Indian troops, although civilian areas in which troops were placed suffered from cholera, plague, small-pox, dysentery, malaria and enteric fever. The hospital admission-rate among British troops was as large as 666 per 1,000 of strength during the year, and was an increase on the rate for the previous year, but the death-rate of 2·75 per 1,000 and the invaliding-rate of 9·14 per 1,000 were lower. Among the Indian troops the death-rate was also down, but the hospital admission- and invaliding-rates were up. This increase, however, was undoubtedly due to the conditions of war service and the return or influx of large numbers of men potentially infected with malaria and other prevalent diseases. Malaria and dysentery held the first place in the list of principal causes of sickness among British officers, and were followed by cellulitis and catarrhal jaundice. Malaria also held the chief place among soldiers, and next came cellulitis, and a good way down tonsillitis; but dysentery came sixth and was only half as frequent as a cause of admission as malaria. The prevalence of dysenteric infections was found to be due to lack of sanitation surrounding the troops' area. Respiratory diseases

were little in evidence, and there were no epidemics beyond minor outbreaks of mild influenza and pharyngitis. Nor was there any sign among the military population of the steady increase in tuberculosis which appeared to be occurring in the civilian population.

George Green Centenary

GEORGE GREEN, author of the famous "Essay on the Application of Mathematical Analysis to the Theories of Electricity and Magnetism", in which appeared for the first time what is now known as Green's theorem, died at Nottingham on May 31, 1841. The circumstances in which a miller was able to engage in mathematical research of fundamental importance have always puzzled the scientific world. New light has been thrown on the problem by Mr. H. G. Green, who has been investigating the matter for several years. In a lecture delivered at University College, Nottingham, to commemorate the centenary, he showed that at least one resident in the locality was well acquainted with the works of the great French mathematicians Laplace and Lagrange, and that the library of the Bromley House Society, of which Green was a member, had no difficulty, even in time of war, in obtaining copies of their researches. Among the members of this Society were several men of high learning and culture, who subscribed for the publication of Green's Essay in 1828. A full account of the investigations will be published in *Osiris*, the journal of the history of science, in due course.

Two French Botanical Pioneers

THE Botanical Garden at Montpellier has grown under the ægis of many distinguished botanists, some of whom made vast contributions to the science without the *éclat* of fame. Dora Maw provides, in a recent article (*J. Roy. Hort. Soc.*, **66**, Pts. 4 and 5, April and May 1941), a chapter of history which shows in vivid fashion the work of two earlier directors of the Montpellier Garden. Pierre Richer de Balleval (1564–1632) was the actual founder, and was a vigorous exponent of the rising science of pharmacognosy. He gathered together a consocies of 1,332 species, lost them during the military manœuvres of inter-religious strife, and started again with characteristic determination. Modern pharmacy owes to him the discovery of galenicals such as *Aristolochia longa, Artemisia campestris* and *Scrophularia aquatica*. Pierre Marie Auguste Broussonet (1761–1807) was a native of Montpellier, and became director of the gardens after a life of epic adventure. He travelled restlessly in south-western Europe and North Africa, after a thrilling succession of political reverses from posts of honour to expedient incarceration. Botanical awareness marked all his journeys, for he brought back knowledge of many useful plants—*Tetraclinis articulata* (citrus wood), *Argania spinosa* (iron-wood), *Acacia gummifera* (the source of gum arabic), and many species of medicinal value. His tenure of the directorship was relatively short, but the background of his extensive travels made it illustrious.

Statistics in Public Policy

MR. H. W. MACROSTY's inaugural presidential address to the Royal Statistical Society, which has now appeared in the *Journal* of the Society, in reviewing the evolution of official statistics in the last fifty years or so, emphasizes their importance for post-war reconstruction. Policy can only be sound if it is founded on a reliable ascertainment of all the facts. Society is never static; our theories must explain and conform to changes which appear to be spontaneously generated and our records must keep step with the changes. No trade policy has any chance of success which is not founded on the most careful study and understanding of the facts, and although the Economic Section of the League of Nations has already provided us with useful comparative studies of the course of international trade in the last twenty years, these do not appear to have penetrated far beyond the study and the lecture room.

Mr. Macrosty also doubts whether we have exhausted the methods of statistical analysis of trade data and whether something more of importance might be learned by the application of some of the methods of modern mathematical research. It is certain that, in the future, nutrition must form the basis of policy, even of international trade, and the repercussion of different lines of policy on each other must be carefully watched. Despite the researches of the last few years, we have still much to learn, and in the collection and study of what is yet unknown, as well as of what is at present known, statisticians are needed for the service of the future. Referring to gaps in our knowledge, Mr. Macrosty pointed out that we have still no quinquennial census; we know little about the distribution of incomes assessed for income tax except in the topmost range; we have no reliable figures of working class earnings and expenditure; calculations of the national income and of savings require much estimation; we have no census of distribution and the monetary and other suggestions of the Macmillan report have not all been adopted although nine years have passed. These statistics are of the most intimate importance for the determination of public policy.

Neanderthal Remains from Hither Asia

THE current number of *Antiquity* as usual contains several important papers. These include among others an article on "The Viking Taste in Pre-Conquest England" with excellent illustrations, and an account of "A Datable Ritual Barrow in Glamorganshire" by Sir Cyril Fox. But perhaps the most important information appears under the "Notes and News" and concerns a prehistoric find in Uzbekistan of flake tool industries associated with the remains of a Neanderthal child. Those who would like more details than this excellent précis can give should consult *Asia* (July and August, 1940) where A. P. Okladnikov has published two interim reports. The discovery itself was made in an immense rock-shelter called Teshik-Tash high up in the side of the Zautolosh Darya gorge not far from Tashkent and the Soviet-Afghan frontier. The rock-shelter is

61 ft. wide and 64 ft. deep ; it is above the contour-levels frequented by shepherds and herds, and so has remained undisturbed by modern intruders. On the other hand, the plentiful remains of wild mountain goats found in the deposits evoke no surprise. There were four black archæological levels separated by clay-like sterile ones, but the industries from bottom to top showed no great culture-change.

The tools are well made of local flinty limestone, quartzite, prase, etc., and include scrapers, disks, flakes and a sort of rough Audi knife (judging from the illustrations) as well as "utilised" bones. There were no real bone tools. It seemed not unreasonable to assign the whole industry to a late Mousterian culture, and this conclusion was confirmed when the skull of a 7–8-year-old child showing unmistakable Neanderthal characteristics was unearthed from definitely within the uppermost archæological level. A point of especial interest was that the skull appeared to have been partly surrounded by a ring of goats' horns arranged in pairs. Indeed, it seems evident that a ceremonial or ritual burial comparable to those of La Ferrassie in France had taken place as far away from western Europe as Tashkent. Geographically nearer, comparisons of implements can be made between the new Teshik-Tash finds and those of such Russian flake-tool sites as Chokurcha, Akhtyr, etc. ; but the appearance of a Neanderthal ritual burial puts the former in a different category, enables a more precise dating to be made, and is intrinsically exciting, opening up as it does new ideas as to the possible distribution of the Neanderthal race.

Radiography of the Chest in Recruits

AT a meeting of the Section of Medicine of the Royal Society of Medicine on May 27, Dr. Philip Ellman read a paper on "Mass Radiography of the Chest in the Early Detection of Intrathoracic Disease, with Special Reference to Pulmonary Tuberculosis in Recruits", in which he maintained that this method offers an invaluable contribution to preventive medicine. He recorded some results which he had obtained by (1) full-sized radiograms, (2) fluoroscopy and (3) miniature screen photography, the last being the most practical means of carrying out mass X-ray examination of the chest. As the result of his experience of this method with control experiments with full-sized radiograms, he suggested that for correct interpretation miniature screen photography demands a technically satisfactory film, which involves the closer co-operation of technician, radiologist and chest physician. The method offers an invaluable contribution to the detection of pre-clinical asymptomatic pulmonary lesions in a presumably healthy population. It can therefore add much to the prevention and control of pulmonary tuberculosis—in war by the examination of recruits, and in peace by the examination of selected groups of the population, for example, where pulmonary tuberculosis is known to be frequent and in certain trades where the pneumokonioses are known to be common. In dealing with the application of the method to cardiology in the detection of cardiovascular lesions, Dr. Ellman urged that serial examinations should be made, and that its general adoption in routine health examinations will be of great value.

The Farmers' Club Library

THE Farmers' Club (2 Whitehall Court, London, S.W.1) has recently added considerably to its library. To extend the use of it, a loan service is being instituted by which members (now numbering 1,320) may borrow books, free of charge. A classified catalogue of the library has been printed, and supplemental lists will be added from time to time. The range of subjects covered is comprehensive, and the dates of publication extend from the eighteenth century up to the present day. Suggestions for additions to the library will be welcomed from members, and inquiries for books not listed in the catalogue may be made as they may be obtainable from other sources. The addition of an author index in any further issues of the catalogue would add considerably to its value

River Flow Records

IT is now two years (June 3, 1939) since there was noticed in these columns an annual report (the third) on Inland Water Survey in Great Britain, issued by the Ministry of Health and the Scottish Office. Unfortunately, there seems to be little or no likelihood that further reports will be published at present. This abrupt cessation of the reports makes a serious hiatus in the useful work of the Survey, which was begun by the Government in 1935 at the instance of the British Association and the Institution of Civil Engineers, and it is greatly to be regretted from a hydrological point of view, since the data collected were, undoubtedly, of great value for a properly systematized estimation of the water resources of the country. To remedy the omission in some measure, Captain W. N. McClean, the director of River Flow Records (Parliament Mansions, Victoria Street, S.W.1), to whose initiative and enterprise the institution of the Survey is due, has just issued a small pamphlet of ten sheets, entitled "River Flow Records of the River Moriston at Invermoriston", giving recorded readings of that river in Inverness-shire during the years 1937–40, in continuation of those which have previously been recorded since 1929. Both water-levels and river flow have been tabulated daily for each month of the period to September 1940. The relationship between them has been established at Invermoriston for any water-level up to an ordinary high flood. Extreme low flow may drop to less than 30 cu. ft. per sec., and an extreme high flood may reach a flow of 16,000 cu. ft. per sec. The area drained is 151 square miles and the run-off for a year of average rainfall is estimated to be about 68 inches. Captain McClean's persistent and painstaking efforts in maintaining these scientific observations are deserving of the highest commendation. It is greatly to be desired that publication of the results of the national survey should be resumed as soon as possible.

Automatic Electrical Farm Boiler

In the *Electrical Review* of June 6, Mr. Theodore Rich gives a complete description of an apparatus developed particularly in the province of Brandenburg in Germany whereby steamed potatoes are prepared for pig food. The steamer consists of a galvanized cylindrical vessel, with an insulating jacket and lid. It is mounted on bearings like a churn, and is fitted with a tipping-locking lever. Three sizes are made for about 80, 155 and 308 lb. of potatoes respectively. The potatoes and necessary water are put in at night, and thanks to automatic control, the potatoes are correctly cooked by the early morning. The food keeps warm throughout the day without the apparatus being switched on and the operational cost is low owing to the special low night rates. The apparatus is protected against running dry. It is claimed that the floury product is much liked by stock.

Basic Costs in Electricity Supply

One of the principal problems in the management of public electricity supply companies is how to reconcile the costs with the charges not only from year to year but also in their irregular secular changes. Cost data are a matter of fact, but the application of such facts to the special circumstances of individual cases is often a question of policy. There are many ways of segregating and arranging cost data, although any process of segregation so far as electricity is concerned is entirely empirical. Some method of averaging has necessarily to be adopted, and probably the greatest difficulty lies in the determination of the proper allowances to be made for load diversity. As Mr. G. D. Bond points out in the *Electrician* of May 2, each extension of the field of development makes the problem harder, and it is hardest when the variety of the load on the public network is the greatest. A modern factor which increases the difficulty of diversity-measurement is arising in those undertakings, where, owing to the development of new loads, there is a consequent shift in the time of incidence of the peak-load.

In addition to the short-term division of costs as 'fixed' and 'running', there is a long-term division of costs into 'differential' and 'residual' costs. This latter division of costs may be explained by considering the domestic and commercial development of load, which is necessarily a long-term process. Up to a point, extra supplies can be given without recourse to additional capital expenditure (particularly when the demands are extensive and not intensive); later on, as local network difficulties arise, some fortification of mains is required, until at a later stage heavy capital expenditure is needed to cope possibly with peak loads of relatively short duration. At this point, the short-term supposition of cost incidence becomes invalid because the differential cost of giving the extra supplies is higher than the residual cost. With intensive development the differential cost decreases provided selective loads are taken to improve consumers' loads and diversity factors.

Franklin Institute Medallists

The complete list of medal awards by the Franklin Institute (see NATURE, July 5, p. 19) is now available: *Franklin Medals:* Sir C. V. Raman; Prof. E. H. Armstrong, professor of electrical engineering, Columbia University; *Cresson Medal:* The United States Navy, received by the Hon. Ralph A. Bard, assistant secretary of the Navy, Washington, D.C.; *Potts Medal:* Prof. H. E. Edgerton, associate professor of electrical engineering, Massachusetts Institute of Technology; *Levy Medal:* Profs. J. M. Lessells and C. W. MacGregor, of the Massachusetts Institute of Technology; *Clark Medal:* Raymond Mower Conner, director of the Testing Laboratories, American Gas Association, Cleveland; *Brown Medal:* W. H. Carrier, chairman of the board, Carrier Corporation, Syracuse; *Wetherill Medal:* H. S. Black, Bell Telephone Laboratories, New York City; *Longstreth Medal:* B. J. Wilson, chief of the mechanical division, Research Department, Leeds and Northrup Company, Philadelphia.

Magnetic Storm

A magnetic storm was registered at Abinger on July 5. The storm began at 6 hr. and remained intense until 16 hr. G.M.T. The range in declination was 1° 17′; in horizontal intensity, 950 γ; in vertical intensity, 745 γ.

Announcements

Prof. Emil Abderhalden, professor of physiology in the University of Halle, has been made an honorary member of the Société de Physique et d'Histoire naturelle of Géneva.

Prof. Piccinini has founded an Institute for the History of Medicine at the University of Milan, where he occupies the chair in that subject.

The University of Oxford is making a grant to the Department of Chemistry to carry out a nutritional survey and a study of antiseptics in relation to burns.

The Ministry of Health is arranging for children attending clinics to have black currant syrup made from a formula drawn up by the Long Ashton Research Station (University of Bristol). Black currants are well known to be very rich in ascorbic acid, and the syrup is stated to contain five times the vitamin C content of orange juice.

The British Psychological Society is arranging a whole-day meeting to be held in London on July 26 to discuss psychological problems of air-raid shelters and evacuation. Those interested should communicate with the honorary general secretary, Mr. R. J. Bartlett, 14 Barchester Road, Harrow Weald, Middlesex.

According to the latest report of the Registrar-General the highest marriage-rate ever known in Great Britain occurred in 1940. Marriages in England and Wales totalled 468,267 and exceeded the record figure in 1939 by 28,573; the marriage-rate per 1,000 of the population was 22·6, and the previous highest rate except for 1939 was 20·2 in 1920. During the War of 1914–18 the highest marriage-rate was in 1915.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Trunk Diameter of Trees of *Hevea brasiliensis*: Experiments with a New Dendrometer

A SENSITIVE dendrometer was designed and constructed at this Institute to study the daily changes which occur in the trunk diameters of rubber trees, and the extent to which the outflow of latex on tapping affects the diameter in the region of the cut. For this purpose there was required an instrument more sensitive than the self-recording dendrograph of MacDougal[1], but optical methods of magnification (*cf.* Mallock[2]) were precluded on account of the difficulty of setting up, protecting and operating the dendrograph in the plantation.

The new instrument consists of a steel U-shaped braced member which carries a system of three levers connected in series, the last one being similar to the Dye optical lever[3] but carrying a light pointer, moving over a scale instead of a mirror, giving a total magnification of about 450. The design of this lever system follows modern practice for precision measuring instruments, all bearings being of kinematic design and the linkages consisting of steel strips so as practically to eliminate friction and backlash. As nickel-iron alloys of low thermal expansion were not available, compensation for expansion of the steel frame was provided by a zinc rod of appropriate length in the lever system, which reduces temperature errors to a negligible value. The instrument can measure rapid small changes of diameter to a limit of about 0·0005 mm.

In use, small metal studs are cemented with grafting wax to scraped areas of the trunk diametrically opposite to each other. The contact points of the instrument, which are 5/32 in. diameter steel balls, engage in trihedral sockets in the studs so as to provide positive location, and the instrument is suspended by chains or wires attached higher up the trunk so that the frame lies horizontally.

Trunks of Hevea trees are found to show a daily variation in diameter similar to that found by MacDougal[1] for many trees of the temperate zone, namely, a rapid diminution starting soon after sunrise or when the sun first strikes the crown of the tree (about 7.00 a.m. Malayan time) and continuing at a diminishing rate throughout the morning and afternoon, tailing off to a minimum between 2 and 3 p.m., followed by a rise which continues during the evening and very slowly throughout the night, reaching a maximum shortly before dawn. This curve closely follows that of atmospheric relative humidity. The daily variation is greatest on hot bright days, when the reduction in diameter at five feet above ground, of a trunk 20 cm. in diameter, may be as much as 0·25 mm. between 8 a.m. and 2 p.m. On rainy or overcast days the total reduction may be only half as much. The trees respond remarkably quickly to changes of insolation; thus in one observation during overclouding of the sun at noon for 22 minutes, a trunk increased in diameter by 0·007 mm., although previously it had been steadily decreasing. An increase was apparent in the dendrometer reading within two minutes of the sun being obscured.

The immediate effect of tapping is clearly shown by the dendrometer. No effect is observed on an instrument mounted above the cut, but on one placed just below a rapid decrease of diameter begins within a few seconds and is often almost complete within 3 minutes of opening the tapping cut. The amount of this shrinkage varies from tree to tree and also appears to depend upon the period since the last tapping and upon the time of day of tapping, but it is usually about 0·03 mm. The effect is less at 50 cm. below the cut but is still quite distinct, and can usually be detected at 75 cm. but not definitely at 100 cm., upon the trees used so far.

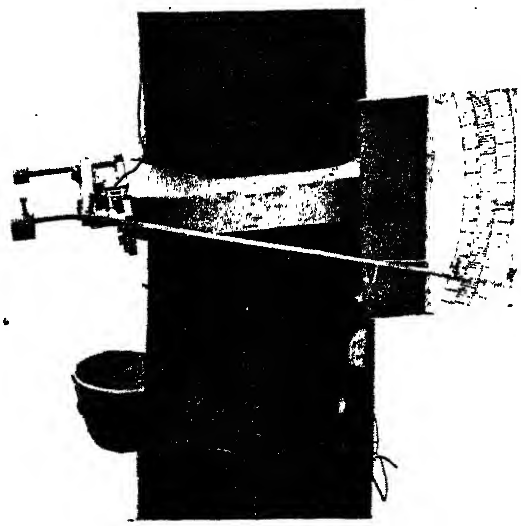

Fig. 1.

FRONT VIEW OF DENDROMETER TO REAR OF TAPPING PANEL.

In early morning tappings, that is, tapping at about 6.30 a.m., the dendrometer records show a recovery to almost the original diameter within about 1½ hours after tapping. A further effect is, however, frequently shown by the tapped tree during the morning and early afternoon following tappings, especially if the weather is hot and dry and no rain has fallen for several days. This is a considerably greater reduction in diameter compared with the records for 'resting' days or with an untapped control tree. Insufficient data have so far been obtained, however, to state definitely whether this effect is general or is a peculiarity of the tree at present under observation.

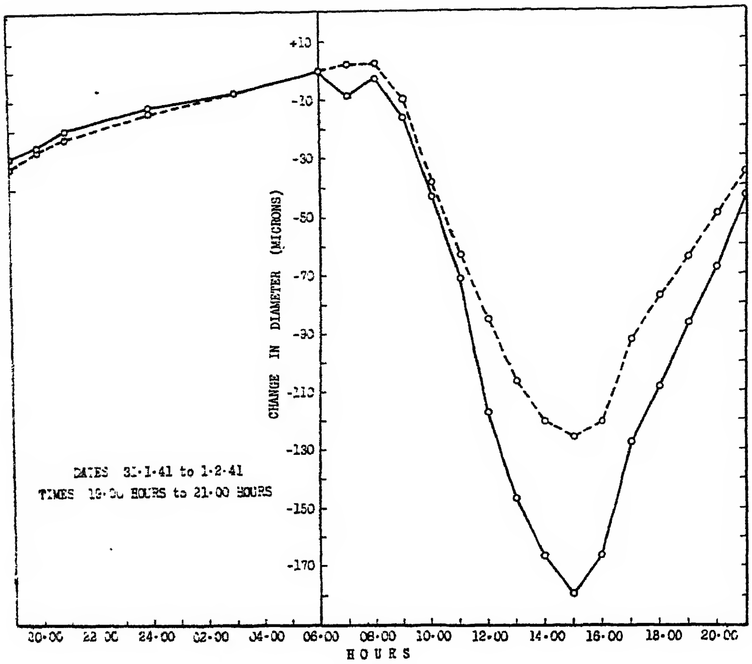

Fig. 2.

GRAPHS OF CHANGES OF TRUNK DIAMETERS IN THE PERIOD OF 19.00 HOURS (31 . 1 . 41) TO 21.00 HOURS (1 . 2 . 41) OF TWO TREES; DENDROMETERS ATTACHED TO EACH AT 84 cm. ABOVE GROUND AND JUST BELOW TAPPING PANELS. *Continuous line:* TREE A, GROSS DIAMETER 19·9 cm. IN 'ALTERNATE-DAY' TAPPING (TAPPED AT 06.35 HOURS, 1 . 2 . 41); *broken line:* TREE B, GROSS DIAMETER 19·6 cm. NOT IN TAPPING DURING THE EXPERIMENT, ACTING AS CONTROL TO A.

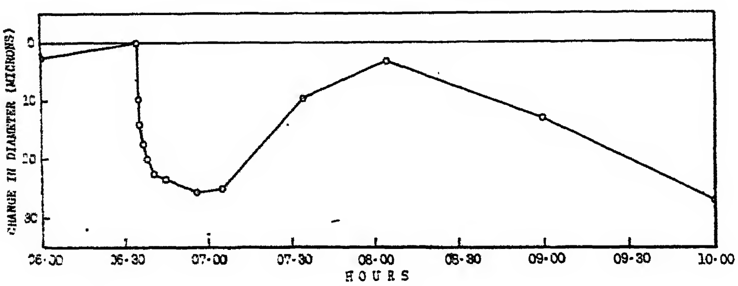

Fig. 3.

IMMEDIATE EFFECT OF TAPPING ON TRUNK DIAMETER JUST BELOW THE TAPPING PANEL. THE TREE TAPPED AT 06.35 HOURS (19 . 2 . 41) SHOWING A REDUCTION OF 25·5 μ WITHIN TWENTY-ONE MINUTES, AND ALMOST COMPLETE RECOVERY WITHIN $1\frac{1}{2}$ HOURS OF TAPPING.

This investigation forms part of a programme of research on the physiology of latex, which was begun at South Kensington under the direction of Prof. V. H. Blackman, with a grant from the Rubber Growers' Association, and is now jointly supported by the British Rubber Producers' Research Association and the Rubber Research Institute of Malaya.

Relative Growth in the Individual

IN view of the criticism[1] that a curve of relative growth derived from contemporaneous data on many individuals of all sizes (population curve) may not apply to actual growth in the individual, as is frequently assumed[4], data on the latter are much to be desired[2]. From careful measurements on series of moults of individual *Carcinus mœnas*, populations of which have been much used for relative growth studies[3, 4], the following conclusions seem to be justified.

(1) Simple allometry[5] does apply to growth in the individual, and is not merely a feature of the population curve; straight-line graphs are obtained by log/log plotting of one dimension against another (see graph on p. 53). For carapace-length/carapace-width in No. 1 there is a single phase of simple allometry from metamorphosis at 1·7 mm. carapace length to the moderately large adult at 45·5 mm. The fitting of the points is so close that these further conclusions are probably justified, in spite of the small number of individuals.

(2) For 'frontal-width'/carapace-width there are two phases of simple allometry (accompanying graph, No. 1). The transition occurs abruptly at a certain moult (the fifth—unfortunately missing from the series). The gradual transition usually seen in population curves may therefore be due to individual variation in body size at transition[6].

(3) For 'dentary-margin'/carapace-width there are similarly two phases, but transition occurs at the third moult, and is therefore probably quite independent of that for frontal width (in these early stages dentary margin is almost a length dimension).

(4) The curve of relative growth between two particular dimensions shows variations in different individuals. There may be variations only in the constant b of the allometry equation $y = bx^{\alpha}$, giving two parallel curves (accompanying graph; Nos. 2, 3; *C.L./C.W.*), or in α also (accompanying graph; Nos. 2, 3; *F.W./C.W.*), in different pairs of dimensions of the same two individuals.

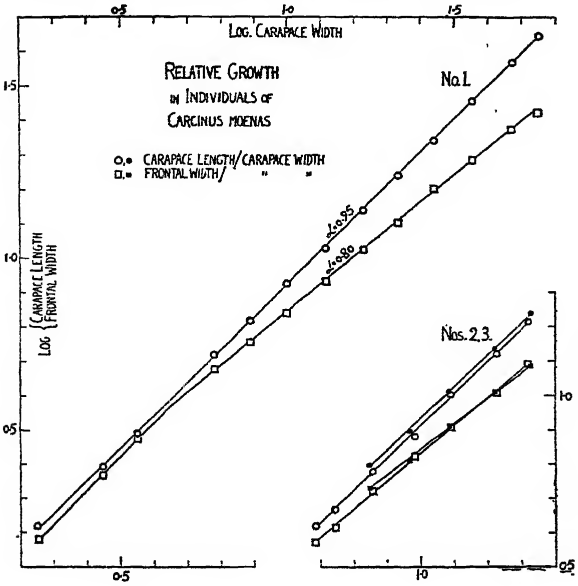
Concerning absolute growth the following points are worth recording:

(5) The increase in body size after each ecdysis is in accord with Brooks's law[7], the constant factor of geometric increase being very near Przibram's constant ($\sqrt[3]{2}$, = 1·26)[8]. The absence of moults 2, 5 in No. 1 is clear. There are small individual differences in the factor.

(6) By contrast to body size the intermoult time increases very irregularly. There is, however, a suggestion of orderliness in a large body of data, and of

a change, about 8 mm. body size, to a more rapid rate of increase. In Corophium[2] the intermoult time is constant over the whole of post-embryonic life.

Data from two short series of both *Maia squinado* and Stenorhynchus sp., and from other short series of Carcinus, essentially support the above conclusions.



(7) In Carcinus No. 1, a female, a record was obtained of the growth in width of the abdominal segments relative to carapace-length, though less complete than that of the carapace dimensions. For the abdomen 1 segment there is a single phase of simple allometry ($\alpha = 1\cdot07$), but for other segments three phases, with the two transitions at approximately 2·5 and 12·5 mm. body size (? metamorphic and adolescent transitions). The transitions are abrupt but the data did not show this to be simultaneous in all segments, possibly owing to the incompleteness of the data. The growth-centre is in abd. 3 segment during the short first phase and in abd. 6 throughout the rest of growth ($\alpha = 1\cdot5$ for 3rd phase) (*c.t.*[3]).

I am indebted to Dr. I. Gordon for the use of the material, from the British Museum Collection.

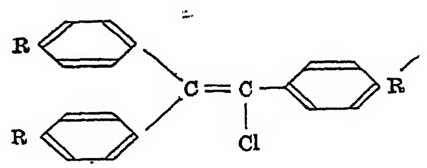
Preparation of Triphenylchloroethylene*

The preparation of triphenylchloroethylene has been effected in various ways [1, 2, 3, 4, 5, 6]. A better mode of preparation of the compound seems to be through the following series of operations.

* Abridged.

To the Grignard reagent prepared from magnesium (12 gm.), benzyl chloride (60 gm.) and ether (250 c.c.), benzophenone (60 gm.) was added, and after two hours' stirring the solution was left for two hours more and then decomposed with cold aqueous ammonium chloride. Ether extracted the carbinol[7] which separated from petroleum (b.p. 70–80°) in colourless crystals m.p. 88–89°. Yield was 80–85 gm. The triphenylethylene[7,8,9] was best prepared by the vacuum distillation of the carbinol (100 gm.) in presence of 2 drops 20 per cent sulphuric acid. It separated from alcohol in colourless crystals m.p. 70°. Yield was 75 gm. To prepare triphenylchloroethylene, sulphuryl chloride (35 gm.) and a solution of triphenylethylene (50 gm.) in carbon tetrachloride (25 c.c.) were mixed together and benzoyl peroxide (0·2 gm.) was added. The solution was refluxed on a water bath for forty-five minutes, excess of sulphuryl chloride was distilled under reduced pressure, and the oily residue was recrystallized twice from alcohol. The mother liquors were concentrated, and the oily material which thus separated was again recrystallized from the same solvent. Triphenyl chloroethylene (45 gm.), m.p. and mixed m.p. 117° was obtained in colourless crystals.



The preparation, on similar lines, of compounds related to triphenylchloroethylene (where R=H. Cl, Br, COOH, Me, MeO, EtO, $\overset{\alpha}{\text{Pro}}$, $\overset{\beta}{\text{Pro}}$, etc., and R′= H, Cl, Br, COOH, Me, MeO, etc., in the formula above) is now in progress.

Catalytic Aromatization and Isomerization of 2.2.4.-Trimethyl Pentane

Hoog, Verheus and Zuiderweg[1] have concluded generally that paraffins with structures not readily permitting the formation of a six-membered carbon ring are not appreciably aromatized or isomerized over cyclization catalysts. While studying the cyclization of hydrocarbon mixtures in these laboratories, however, it was found that at 550° C. with a liquid catalyst-space velocity of 0·33 c.c./c.c./hour

and a 6 atomic per cent molybdenum oxide-activated alumina catalyst in a mild steel catalyst tube, considerable formation of aromatics from pure 2.2.4. trimethyl pentane resulted, accompanied by cracking. The aromatics contained mixed xylenes, *o*-xylene being identified, together with some naphthalene.

The full results will be published elsewhere.

Use of the Term 'Resolving Power' in Spectroscopy

THE classical description of the limit of applicability of an instrument by the resolving power $\lambda/d\lambda$ has been used in spectroscopy for many years in spite of very obvious drawbacks. Since the advent of the Bohr theory of spectra, the spectroscopist is not concerned with *wave-lengths* but with *frequencies* and *frequency differences*. If a concept of the power of instruments to resolve close lines is adopted in terms of frequencies, there results a considerable improvement in clarity and in practical applicability.

Consider as typical examples the use of a Fabry–Perot interferometer and of a grating to separate close components. The interferometer, air gap of thickness $t = 1$cm., is coated with aluminium mirrors having a uniform reflecting coefficient between 5,000 A. and 10,000 A. The grating has 100,000 lines to the inch and is to be used in the first order. Consider the use of the instruments for the resolution of close lines at 5,000 A. and 10,000 A.

With the interferometer the frequency difference which can be resolved at any wave-length is $d\nu = dn/2t$; that is, resolution depends only upon the fraction of an order dn which can just be separated with the gap used. This does not involve the wave-length if we have a uniform reflecting coefficient (the same is effectively true with the Lummer plate). The *shapes* of the fringes at 5,000 A. and 10,000 A. can be considered to be identical and as a result the *same* frequency difference can just be resolved at these two wave-lengths, or at any in between. The effectiveness or practical 'power' of the instrument is therefore *uniform* over the whole range. But if we evaluate $\lambda/d\lambda$, we find that the resolving power in the strict classical sense increases regularly with diminishing wave-length, being in fact twice as great at 5,000 A. as at 10,000 A. Clearly, as a description of the effectiveness of the instrument the resolving power is undesirable and should be modified.

With a strictly monochromatic source any instrument produces an apparent line width, owing to diffraction, etc., and it is, of course, this which sets the lower limit to the resolution. Instead of regarding this width as a wave-length difference, the frequency difference should be considered.

I propose that instead of using resolving power we define the ability of an instrument to resolve lines at any wave-length by $d\nu = \nu.d\lambda/\lambda$, that is, by the *instrumental line width in cm.*$^{-1}$ *at that wave-length.* This quantity, being equal to the wave number of a line divided by the classical value of resolving power, can readily be evaluated. A convenient name for this quantity would be the *resolving limit*, and it will be seen that it is a practical measure of the effective applicability of an instrument and in actual practice of more use than the classical resolving power. Thus in the interferometer, the line width is a certain fraction of an order (depending only upon the reflecting coefficient) divided by twice the gap. With a good instrument a fringe is 1/20 of an order wide; hence for the case under consideration the *resolving limit* is 0·025 cm.$^{-1}$ over the whole range 5,000–10,000 A. This is a practical index of the performance.

That the proposed new definition is superior to the classical resolving power is clearly demonstrated by considering the grating. The resolving power $\lambda/d\lambda = nm$ (in this case 100,000) is uniform over the whole wave-length range. On the other hand, the *resolving limit*, the *smallness* of which is the significant criterion, is proportional to ν, its value being $d\nu = \nu/nm$. It is thus half as much at 10,000 A. (namely, 0·1 cm.$^{-1}$) as at 5,000 A. (0·2 cm.$^{-1}$). It is therefore clear from this quantity that the farther one goes in the infra-red the better adapted is a grating for the resolution of close structures. This is a property not immediately obvious from the classical definition of resolving power, and rarely emphasized.

These two simple examples suffice to show that the classical resolving power as an index of an instrument should be replaced, for similar difficulties arise with any instrument employed over a wide wave-length range.

"'Pancake' Ice in the Pennines"

SINCE my letter on the above subject was published in NATURE of May 3, I have received one or two communications commenting on the phenomenon, to which it may be of further interest to refer.

Mr. R. I. Lewis has kindly directed my attention to a note by his friend Mr. D. J. P. Phillips, of University College, Cardiff, which appeared in NATURE of February 5, 1914, under the title "A Curious Ice Formation". Having now had the opportunity of referring to the latter, I find that the short description given suggests quite clearly a parallel occurrence of 'pancake' ice formed under similar, though somewhat more artificial, conditions to those I described at High Force in Upper Teesdale. Mr. Phillips's illustrated example exhibited circular floes of ice encrusted with snow and having the appearance of water-lilies. They were found in the River Ure at Brecon where it had just passed over a weir, and they were apparently formed following the night of December 31, 1913, when 14° of frost had been registered locally.

From Mr. Henry Bury, of Bournemouth, I have received a short description of 'pancake' ice seen by him on January 23, 1933, on the River Loire at Gien (Loiret). He records that circular rafts of ice estimated at 4–6 ft. diameter, and covered with snow, were being carried along in a flooded and swiftly flowing river. The whirling motion imparted to these rafts, and the frequent collisions between them, were, in Mr. Bury's opinion, sufficient to account both for their form and for their conspicuous raised borders.

Consequently, it would seem amply clear that, under suitable and sufficiently 'rigorous' conditions, 'pancake' ice can be formed in other than the polar regions.

N. E. ODELL.

RESEARCH ITEMS

Distribution of types of *C. diphtheriæ*

H. D. WRIGHT has analysed the incidence, severity and age-distribution of 8,040 infections caused by the three types of *Corynebacterium diphtheriæ* (*J. Path. and Bact.*, **52**, 283–294; 1941). The cases were notified in Liverpool during the four years 1937–1940; and there were 475 deaths (5·9 per cent). The *mitis* type was cultivated from 29·8 per cent, the *intermedius* type from 18·9 per cent, and the *gravis* type from 51·3 per cent of the total cases of diphtheria in the period under review. The figures show that the incidence of the *gravis* type increased each year from 34·2 per cent in 1937 to 69·6 per cent in 1940, but that the *mitis* and *intermedius* incidence correspondingly decreased. The proportion of the *mitis* cases in each year that were included within the age-group 0–4 was higher than that of the *intermedius* and the *gravis* cases in this age-period; and, similarly, the *intermedius* percentage figures were higher than those of the *mitis* type for the ages 10–14. The case-fatality rate, over the whole period, of infections with *mitis* was 2·2 per cent; for *intermedius* it was 10·7 per cent; and for *gravis* it was 6·3 per cent. The proportion of toxic cases was considerably greater in the *intermedius* and *gravis* groups than in the *mitis* group. The author discusses the validity of subdividing strains of the diphtheria bacillus into the above-mentioned types. This classification originated ten years ago in Leeds and has been widely confirmed, although critical reports have recently come from the United States. The Liverpool experience has convinced Wright that the types are founded on well-established criteria; that, with practice, they are readily distinguishable; and that they serve a useful purpose in helping to make clear the pathological and epidemiological features of the disease.

Isotopic Constitution of Potassium *in vivo*

POTASSIUM is known to have three natural isotopes $^{39}_{19}K$, $^{40}_{19}K$ and $^{41}_{19}K$. The 39 isotope represents the bulk of the element, the 41 isotope a relatively small fraction, while the radioactive 40 isotope occurs only in minute quantity. It is known that the abundance ratio of the 39 and 41 isotopes is not a constant figure for all organic tissues. A. Lasnitzki and A. K. Brewer (*Biochem. J.*, **35**, 144; 1941) have now studied the isotopic constitution of potassium present in various rat tissues by mass-spectrographic measurement on the ash. In the living animal a continuous potassium exchange takes place between the various tissue cells and the blood plasma. The actual potassium content of tissues is on the average perhaps twenty times higher than that of blood plasma. It was found that the isotopic ratio $^{39}_{19}K/^{41}_{19}K$ in the ashes from bone marrow and blood plasma was distinctly lower than that of ordinary mineral potassium (purified KCl) or from the ashes of other tissues. A kinetic mechanism has been proposed accounting for the observed effect depending on the condition that the intracellular potassium, in contrast to the extracellular potassium, is completely associated with heavy molecules. A fractionation of the 39 and 41 isotopes due to the difference in velocity of the ions in their passage through the cell membrane thus occurs. The isotope ratios of tissue potassium and plasma potassium do not depend solely on the mechanism responsible for their difference, but also on the isotopic ratio of the potassium which enters the blood-stream via the intestine. Fractionation of isotopes due to slight differences in chemical properties can be obtained by exchange reactions. Thus if zeolites containing sodium as a basic constituent are brought into contact with solutions of lithium or potassium salts, the sodium is exchanged for lithium or potassium, but the light isotope of lithium and the heavy isotope of potassium are taken up preferentially.

Genetics of Cotton

S. C. Harland and O. M. Atteck (*J. Gen.*, **42**, 1–21; 1941) have given important facts regarding the genetics of cotton. They have been able to introduce genes from the diploid *Gossypium Thurberi*, *G. Armourianum* and *G. aridum* to the tetraploid *G. barbadense* and *G. hirsutum*. By continual back-crossing they were able to study the effect of one gene on the background of *barbadense* and *hirsutum*. The *Armourianum* petal spot due to S^{arm} was proved to be an allelomorph of *hirsutum* R^h. On a *hirsutum* background, the size of the petal is not reduced in size or intensity. S^{ari} of *G. aridum* is another allelomorph of R^h. The character is reduced on a *hirsutum* background, where it becomes mutable, although it is stable in *aridum*. The evidence that S^{ari} of *aridum* and S^{arm} of *Armourianum* are allelomorphic to R^h of *G. hirsutum* provides proof that the tetraploid New World cottons contain two genoms of Asiatic and North American affinities respectively.

Sex-linked Albinism in the Fowl

A USEFUL new gene (*al*), giving a dingy white, pink-eyed chick, is reported by C. D. Mueller and F. B. Hutt (*J. Hered.*, **32**, 71–80; 1941). As the fowls grow, some melanin is found in the eye and a ghost pattern may be seen on the plumage. Sight, viability and productivity appear to be normal. The gene is sex-linked and raises to nine the number of genes known to be carried on the sex chromosome. It is highly probable that the mutation was found in the first generation after its occurrence.

Cyanogenesis in Lotus

ONE form of *Lotus corniculatus* liberates hydrogen cyanide when its leaves are killed, while another form morphologically indistinguishable from the first is acyanogenetic. Cyanogenesis is inherited in a tetrasomic manner as a dominant (C. D. R. Dawson, *J. Gen.*, **42**, 49–72; 1941). The observed numbers approximate to those expected on chromosome segregation. Cytological examination shows that this species is a tetraploid with $2n = 24$ chromosomes, but that quadrivalents are rare. The author points out that genetical data of segregation are safer than cytological as a criterion of autopolyploidy. It is considered that *L. tenuis*, which also has both acyanogenetic and cyanogenetic forms, is a diploid relative of *L. corniculatus*.

Reaction of Aliphatic Amines with Nitrous Acid

IT might be assumed that primary aliphatic amines of low molecular weight would react easily with nitrous acid to form primary alcohols with liberation of nitrogen according to the equation: $RNH_2+HNO_2=ROH+N_2+H_2O$, and this reaction has been shown to occur with butylamine to the extent of 25 per cent. Very little information is available on the general aspects of the reaction. F. C. Whitmore and R. S. Thorpe (*J. Amer. Chem. Soc.*, **63**, 1118; 1941) have examined the effect of nitrous acid on methylamine, ethylamine and *n*-propylamine under varying conditions. In sixteen experiments with methylamine and nitrous acid under a wide variety of conditions, no methyl alcohol or other reaction product could be isolated from the reaction mixture, some methylamine being always recovered unchanged. The amount of unchanged amine was never less than 25 per cent, and was sometimes more than 90 per cent, although conditions like those employed with *n*-butylamine were used in several cases. Solvents other than water were also used, and a reaction in the gas phase with methylamine, nitrous vapours and a trace of moisture was attempted. The amine nitrite seems to be more easily hydrolysed than decomposed. Small amounts of methyl alcohol were obtained with silver nitrite and methylamine hydrochloride. Ethylamine with nitrous acid gave a 60 per cent yield of ethyl alcohol; *n*-propylamine gave 7 per cent of *n*-propyl alcohol, 32 per cent of isopropyl alcohol and 29 per cent of propylene. Traces of ether were also formed with ethyl and propyl amines.

The Antimony Electrode

MANY investigations have been carried out on electrodes of the metal–metal oxide type. The only one of them which has met with much success is the antimony–antimony oxide electrode. The values reported in the literature for the standard potential and the slope of the *p*H curve vary widely. F. Hovorka and G. H. Chapman (*J. Amer. Chem. Soc.*, **63**, 955; 1941) have obtained very satisfactory antimony electrodes by casting pure antimony (obtained by electrolysis from hydrofluoric acid solution) into sticks under reduced pressure. These castings were free from surface pits and were very lustrous; they were cleaned by electrolysis in sodium carbonate solution and repolished before use. The sticks were immersed directly in the buffer solutions and the other electrode was a hydrogen electrode. It has been known for some time that it is unnecessary to add any antimony oxide. The potential at 25° was found to be $0{\cdot}2552 - 0{\cdot}05893\ p\text{H}$ referred to the normal hydrogen electrode, a deviation of the potential at $p\text{H}=8$ reported by other investigators being confirmed. Between *p*H 2·2 and 8 the slope of the curve was constant, and the value 0·05893 is quite close to the value 0·05912 predicted by the Nernst equation.

Heat Capacity of Nickel Sulphate

ONE of the more important problems arising from the use of the third law of thermodynamics is the persistence of multiple electronic states in some solids at low temperatures. This is indicated by a change of magnetic susceptibility with temperature. Heat capacity measurements give no indication of the entropy contribution due to these states unless they are carried to such low temperatures that the electronic contribution is 'frozen out'. In a study of the heat capacity and magnetic susceptibility of nickel sulphate heptahydrate, $NiSO_4$, $7H_2O$, at liquid helium temperatures, Stout and Giauque (*J. Amer. Chem. Soc.*, **63**, 714; 1914) find that the electronic system makes a large contribution to the heat capacity at temperatures where the lattice energy is unimportant, and there is a maximum in the heat capacity about 1·8° abs. The entropy contribution associated with the electronic system is shown to be R ln3, which shows that the system has three electronic levels. These are about equally separated by about 2·6 cm.$^{-1}$, equivalent to 7·4 cal. mol^{-1}. The character of the heat capacity curve of the substance down to 15° abs. gives no indication that electronic entropy exists, so that if it were extrapolated on the assumption that no abnormal change would occur at much lower temperatures, the calculation would be in error by 2·2 cal. deg.$^{-1}$ mol^{-1}. The adiabatic change of temperature on magnetization was also measured.

Ionization of Sulphurous Acid

IT is established that sulphurous acid ionizes in two stages: $SO_2 + H_2O \rightleftharpoons H_2SO_3 \rightleftharpoons H^{\cdot} + HSO_3{}'$ $\rightleftharpoons 2H^{\cdot} + SO_3{}''$, and the values of the two dissociation constants have been determined. The first ionization constant has been calculated fairly recently, but with the assumption that the activity coefficient of sulphurous acid is the same as that of hydrochloric acid for the same ionic strength. The second ionization constant had not been determined by a modern method. H. V. Tartar and H. H. Garretson (*J. Amer. Chem. Soc.*, **63**, 808; 1941) have determined both constants by electromotive force methods involving the use of glass electrodes containing suitable buffer solutions. For the first constant the electrolyte was a solution containing sodium chloride and sodium hydrogen sulphite with excess of sulphur dioxide, and for the second dissociation constant the solution contained sodium chloride or bromide, sodium sulphite and sodium hydrogen sulphite, the terminals at each side of the cell being silver and silver halide in both cases. A special investigation of the solubility of silver chloride in sodium sulphite disclosed the existence of the complex ion $Ag(SO_3)_2{}'''$. The values of the thermodynamic dissociation constants at 25° found were: $K_1=1{\cdot}72\times10^{-2}$ and $K_2=6{\cdot}24\times10^{-8}$. The first is in fair agreement with previous determinations by conductivity methods; the second is only in qualitative agreement with other reported values made by much less accurate methods.

Researches on the Meson

THE mesons (mesotrons) found in cosmic radiation are supposed to be capable of spontaneous decay. W. M. Nielsen, C. M. Ryerson, L. W. Nordheim and K. Z. Morgan (*Phys. Rev.*, **59**, 54) have measured the mean lifetime of the meson by comparing the intensity of the hard cosmic rays under a graphite block on top of a mountain with the intensity measured at a lower altitude under an additional layer of atmosphere equivalent in mass to the carbon. The absorption of the mesons in the air and the carbon is the same, and the lower intensity under air is ascribed to the spontaneous decay of the mesons in the time required to traverse the air layer. The calculations of mean lifetime do not depend on assumptions regarding the energy distribution of the particles or the height in the atmosphere at which they are produced. The result obtained is about 1·25 microseconds (for a meson mass 200 electron masses), which is appreciably shorter than previous estimates. Nordheim (*ibid.*, **59**, 554) calculates the ratio of hard and soft component

of the cosmic rays at sea-level, taking this decay period, and considers that the soft component observed is smaller than that calculated on the view that the products of decay are a proton and an electron, and he suggests that some of the energy is carried off by neutrons. F. Rasetti (*ibid.*, 59, 613) has used a coincidence counter system to count occasions on which a meson is absorbed in iron and a shower is emitted after a delay of a few microseconds. This event is supposed to be the stoppage of a meson followed by decay and the emission of an electron which initiates a shower, and an analysis of the delay results indicates that the life of the meson at rest is about 3 microseconds. L. Leprince-Ringuet, S. Gondelsky, E. Nageotti and R. Richard-Foy (*ibid.*, **59**, 460) have analysed a cloud-chamber photograph of a collision between a cosmic ray meson and an electron. The collision took place in a magnetic field, and by good fortune all the track curvatures are suitable for accurate measurement. The mass of the meson is therefore obtainable and the authors estimate it at 240 ± 20 electron masses.

A Neutrino Theory of Stellar Collapse

G. Gamow and M. Schoenberg (*Phys. Rev.*, **59**, 539) have suggested a novel process to account for the appearance of stellar novæ. At the very high temperatures and pressures which exist in the deep interior of a contracting star, nuclear processes may be expected in which neutrons are formed. These particles can escape from the interior without giving up energy, and thus provide a mechanism for cooling the star from the centre. As the centre of the star collapses from this cause, layers just outside the centre are left unsupported and fall in, much gravitational energy being converted into heat. It is shown that the process which takes place involves simultaneously the collapse of the inner layers and the rapid expansion of the outermost layers, with great increase in the luminosity of the star. The process grows more and more violent as the pressure and temperature of the central regions increase. The marked difference between 'novæ' and 'supernovæ' is probably to be ascribed to a difference in mass, since it has previously been shown that a star having less than a certain central mass contracts to a stable configuration of definite radius while bigger stars are subject to unlimited contraction.

The Great Spot on Jupiter in 1939

B. M. PEEK has discussed his twenty-five observations of a dusky spot at the north edge of the South Temperate Belt of Jupiter during July 31–Dec. 21, 1939 (*Mon. Not. Roy. Astro. Soc.*, **101**, 2; 1941). On plotting these observations against the time, they suggested a damped oscillation of some kind, superposed upon a fairly uniform decrease of longitude. Wildt and Peek have shown that the density of Jupiter's atmosphere must increase very rapidly with the depth, unless the internal temperature is high, and it is fairly certain that in the lower strata the gas is practically indistinguishable from a liquid except for the absence of a bounding surface. In his presidential address to the British Astronomical Association (*J. Brit. Ast. Assoc.*, **50**, 2; 1939), Peek expressed the view that masses of light solids which were floating in denser gases might explain some of the surface phenomena of the planet. It is now suggested that the spot observed was associated with the presence of a solid body performing vertical oscillations near the level at which it would have floated in equilibrium. It is possible to derive the density gradient and also the compressibility of the atmosphere at the equilibrium level from the hypothesis. Unfortunately for the hypothesis, the compressibility should be multiplied by a factor 10^7 to make it commensurable with the compressibility of typical fluids.

Dimensions of the Andromeda Nebula

THE great nebula in Andromeda, as seen visually on suitably exposed negatives, can be easily contained in an ellipse measuring $3° \times 1°$. Direct photo-electric measurements made at the focus of the 100-in. telescope at Mt. Wilson have suggested that in reality it extends nearly to $6° \times 1{\cdot}5°$. R. C. Williams and W. A. Hiltner (*Pub. Obs. Univ. Mich.*, **8**, 103; 1941) have recently extended these limits still farther on a long-exposure Mt. Palomar photograph taken with the 18-inch $f/1{\cdot}9$ Schmidt camera. The direct-intensity microphotometer used for tracing isophotes on this negative easily measures a density difference of 0·003, and shows that the apparent diameter along the major axis must be at least 6·7°, corresponding to a real diameter of 80,000 light-years. The surface luminosity at these outer regions is only about 27·8 mag./sec.². The outer isophotes reveal two hitherto unsuspected elongated extensions of the nebula lying on opposite sides of the major axis and suggesting a slight counter-clockwise curvature, though the well-defined inner arms are curved clockwise. This work still further reduces the discrepancy in size between the Andromeda nebula and our own galaxy: we must now regard ourselves as inhabiting a galaxy the dimensions of which, though large, are not of a different order of magnitude from those of neighbouring nebulæ.

Birth Distribution of Sunspots

G. H. A. ARCHENHOLD has constructed a frequency curve of observed first appearances of sunspots (*Mon. Not. Roy. Astro. Soc.*, **101**, 2; 1941). The work is based on Minnaert's method (*Astron. Nach.*, **263**, 13; 1937; also **268**, 81; 1939) with slight modifications. Minnaert's construction gives, for any individual form of life-curves of sunspots, the number of spots which reach the minimum size necessary to be detected in a given interval of longitude. But this theoretical number can only be compared with the one observed at that longitude if the first appearances of sunspots were recorded by continuous observation, and as most statistics are based on daily observations, the first appearances are registered too late—in other words, they are registered in a more westerly position. In addition, spots having a duration of less than 24 hours may completely escape observation. The mean daily synodic motion of a sunspot is 13·2°, for which reason, in the case of daily observations, a spot will be seen somewhere in the interval of 13·2° following the point where it reaches the limit of visibility, and Archenhold adopts this procedure to make the theoretical results comparable with the observations. A full explanation with examples is given. The curve of visibility derived for the Greenwich instruments has been applied, as the results of the investigation are compared with the Greenwich observations. The figure representing the birth distribution shows a very decided correspondence between the theoretical distribution and that observed at Greenwich between 1886 and 1935. It justifies certain assumptions which the author has made on the curve of visibility, on the form and number of the life-curves of spots, and on the intervals in which the observations of the sun are made.

THERMAL EFFECTS IN TRANSFORMATIONS IN METALS

"THERMAL Effects in Transformations in Metals" was the title of a lecture delivered on May 13 by Dr. C. Sykes, superintendent of the Metallurgy Department, National Physical Laboratory, to the London and Home Counties' Branch of the Institute of Physics in the lecture hall of Messrs. Kodak Ltd., Harrow.

Dr. Sykes instanced the change which occurs during the cooling of eutectoid steel as a familiar and typical phase transformation. This transformation from face-centred γ-iron to body-centred α-iron and iron carbide (Fe_3C) has formed the subject of many investigations, and its suitable control has led to important variations being realized in the properties of steel. The temperature at which a transformation takes place has usually been determined from observations on either the direct cooling curve or the inverse-rate curve, or is deduced from the microstructures of samples which have been quenched or slowly cooled from various temperatures. In recent years the limitations of these methods have become apparent. The furnace-cooling methods clearly define the temperature at which a transformation commences, for there the energy released within the specimen causes a definite change in its rate of cooling. This change in rate has but little effect on the cooling of the more massive furnace, and the resultant variation in the difference in temperature between the furnace and the specimen affects the rate of cooling of the latter, so that great care is needed in the interpretation of subsequent results. In the case of β-brass a transformation occurs which commences at about 460° C. and continues down to about 160° C. Transformations of this type require entirely new methods of thermal analysis. Furthermore, since the change consists merely of a rearrangement of the atoms within the solid solution, an examination of the microstructure is no longer helpful.

Little progress was made in the study of such transformations until Tammann observed that they nearly always occur with binary alloys of the types XY and X_3Y. For the body-centred cubic crystal CuZn (β-brass), he suggested that, whereas at high temperatures the atoms are randomly arranged, at low temperatures the copper and zinc atoms are each on separate lattices. Thus, on cooling, heat will be evolved as the atoms settle into the more orderly arrangement. The theory of an ordering process based on similar assumptions to those of Tammann has been worked out by Bragg and Williams. They introduced the quantity s to represent the degree of order of the alloy, and postulate that $s = 1$ corresponds to perfect order and $s = 0$ to complete disorder, that is, the random arrangement. For an XY alloy such as CuZn, it is shown that s can be represented by $\tanh(V/4kT)$, where V, the energy required to interchange a Cu and Zn atom, is not constant but equal to sV_0. These equations have been solved for s as a function of T.

There is shown to be a definite critical temperature, T_c, where the value of s commences to rise steeply from zero and to tend asymptotically to unity at a lower temperature. The X_3Y alloy differs in that s rises from zero to a finite value at T_c and then shows a similar increase towards unity at lower temperatures. It is possible to calculate the energy changes associated with these transformations and so to predict the variation of specific heat with temperature. The transformation should cause the specific heat to exceed the normal value, to rise to a sharp maximum at T_c, and then fall back on to the normal curve. With an alloy of the X_3Y type there should be a definite latent heat at T_c. In the Bragg–Williams theory the average degree of order in the whole crystal has been considered, and a slightly modified result has been obtained by Bethe, who defines order from considerations of the nature of the neighbouring atoms around a given atom of either kind in the structure. Bethe's theory predicts that although superlattice order disappears at the critical temperature, a high degree of local order persists, giving an abnormally high specific heat, which only vanishes at very high temperatures.

At this stage the need for more precise methods for the determination of specific heats over wide ranges of temperature became imperative, and Dr. Sykes was responsible for the development of a method which proved highly satisfactory. The specimen, in the form of a small cylinder fitted with an internal heating coil, is mounted inside a cylindrical copper block from which it is thermally insulated. The whole is inserted in a furnace and can be evacuated. Now suppose the furnace is so controlled that the temperature of the copper block increases at a constant rate, then the temperature of the specimen will rise along a lower curve. If, however, energy is generated in the coil within the specimen, it is possible to bring the temperature of the latter above that of the furnace. At the instant at which their temperatures are the same, no external heat is received by the specimen and so $Q = MC_p(dT/dt)$, where Q is the power supplied to the specimen, C_p its instantaneous specific heat and dT/dt the rate of temperature rise of the specimen. By suitable manipulation of Q, the temperatures of specimen and furnace can frequently be brought into equality and a series of determinations of C_p can be made at increasing temperatures.

Much skill and ingenuity has been used in the development of the apparatus, and the accuracy obtainable is $\pm$ 1 per cent at 400° C. and $\pm$ 2 per cent at 600° C. It has been possible to ensure that the temperature of the specimen does not depart from that of the block by more than 0·1° C. Under these conditions the experiment can be modified to give the total heat content for a specified range of temperature. When this is done, the specimen heater current is passed through a copper voltameter so as to obtain an integrated value of the power supplied.

Detailed experimental results were described for two alloys, CuZn and Cu_3Au. For CuZn the total energy associated with the ordering transformation was found to be 9·8 cal./gm., whereas the Bragg–Williams theory gave 11·4 and the Bethe theory 10·8 cal./gm. Above the critical temperature the specific heat remains abnormally high, owing presumably to the presence of local order.

Further confirmation that β-brass undergoes an order–disorder transformation has been obtained from

X-ray spectrographs. Extra lines, the so-called superlattice lines, have been observed in X-ray photographs of the ordered structure taken with zinc radiation.

Cu_3Au has a face-centred lattice with gold atoms at the corners of each cube and copper atoms at the centre of each face. In this instance it is easy to establish the existence of a superlattice by means of X-ray analysis; in fact, an idea of the completeness of the ordering can be formed from an examination of the intensities of the superlattice lines. The thermal measurements, on the other hand, are somewhat more complicated owing to the slowness with which equilibrium is attained. To overcome this difficulty the following technique had to be adopted. From 420° C. upwards it was found that the specific heat curve was independent of the initial state of the alloy, so presumably it was always in equilibrium at this temperature. The effect of temperature on the energy content was therefore obtained by annealing a specimen at a temperature T until equilibrium was attained and then measuring the energy necessary to heat the alloy from T to 420° C. Since the specimen is in equilibrium both at the beginning and end of the experiment, the energy input to the specimen heater is equal to the difference in equilibrium energy contents corresponding to the initial and final temperatures, although at intermediate temperatures the alloy need not be in equilibrium. The anticipated latent heat is observed and the general agreement with theory is reasonably good, although neither theory gives a correct representation of the release of energy near the critical temperature. The Bragg–Williams theory gives a curve rising too slowly with decreasing temperature, and Peierls's (who has applied Bethe's theory to this alloy) theory gives too great a latent heat.

Other alloys which have been examined are Cu_3Pd and Ni_3Fe, and in both cases fairly good agreement with theory has resulted. Ni_3Fe, which closely resembles mumetal, is of interest in that it has been found that the best magnetic properties are obtained when the alloy is in a state of partial order.

The development of these precise methods of thermal analysis are thus seen to have done much to remove the difficulties which metallurgists have encountered in dealing with order–disorder transformations. R. W. POWELL.

EFFECT OF THE WAR ON BIRD LIFE

By R. S. R. FITTER

RECORDER OF THE ORNITHOLOGICAL SECTION, LONDON NATURAL HISTORY SOCIETY

VERY little is yet known about the effect of the War on bird life in Britain, though the secretary of the British Trust for Ornithology has appealed for information on the subject. It is easy enough to make a number of theoretical deductions from the known variations in ecological and other factors. The decrease of gamekeepers' activity should result in an increase of hawks and owls; the increase of arable and decrease of pasture land is bound to affect the balance of Nature in various ways; the felling of many woodlands will certainly make the woodland birds scarcer after the War; the reduction in the number of oil-discharging boats frequenting the British seas should result in a smaller death-rate among sea-birds; and so on.

A good many scattered records about the actual effect of the War on bird life have appeared in various journals, and should be collated. The present article is based on records sent in to the London Natural History Society during the past year.

Actual casualties among birds appear fortunately to have been very few. A research-worker in the north of England wrote asking to be sent the corpses of any starlings that might be found lying about London after a night of air raid, but though the starlings still come in to roost in London every night, I have not heard of any being killed in an air raid, though doubtless a large number have been. The only definite casualty reported is a missel-thrush killed by a bomb explosion in Hertfordshire. It was found dead thirty yards from where the bomb burst, and there was a wooden fence in between.

Several records have come in of birds taking fright at day-time bomb explosions. The explosion of delayed-action bombs in one area sent a heron screaming over a neighbouring garden, and on another occasion eight crows flew over after a similar explosion. From the same area comes a report that heavy gunfire sends the gulls home to roost early. A barn-owl, on the other hand, has been reported screeching during an anti-aircraft barrage, while a swift was seen circling around quite unperturbed by an air battle going on overhead. A green sandpiper, too, was not driven from its customary roosting-place by the fact that three bombs fell in a neighbouring field, while in two heronries numbers breeding in 1941 were undiminished in spite of many bombs falling in unpleasantly close proximity. Once a wheatear was seen flitting about over the wreckage in one of the worst devastated areas of the East End.

House-sparrows, too, have shown their enterprise. In one suburban town they were quick to explore the new nooks and crannies in a bombed house, and showed a marked partiality for new putty, possibly because of the linseed oil it contained. One result of the bombing of London has been to provide an abundance of potential nesting sites for the black redstarts, which are showing a tendency to colonize London. So far, however, the birds which have appeared in 1941 have favoured only Westminster Abbey, where they bred last year, and the British Museum (Natural History) in South Kensington, where they have been reported in several previous years.

Not many effects of the War on birds' feeding habits were reported, but a large number of black-headed gulls, together with several great and lesser black-backed gulls and carrion crows were seen feasting on the fish apparently killed by bombs falling in the Thames. When two small lakes were drained, black-headed gulls came and cleared the mud of mussels.

The activities of soldiers have had a detrimental effect on bird life in at least one area, where smaller numbers of redstarts and whitethroats are reported to have nested, as a result of military operations, and a cock whinchat disappeared after being alarmed by

soldiers training. No adaptation of nesting habits to war-time changes has been reported that equals the resourcefulness of the sand-martins that nested in a trench dug for military training near Gidea Park Station in 1917.

OBSERVATIONS FOR THE CAPE ASTROGRAPHIC ZONE

THE work which the Royal Observatory, Cape of Good Hope, undertook on the Astrographic Zones − 40° to −52° has been completed and is now available in the volume referred to below*. It was felt that the value of the work would be greatly increased if the spectral types were also given and accordingly these were entered in the copy for the Press from the Henry Draper Catalogue. Owing to the faintness of the stars, however, spectral types were available for only a very limited number, about a quarter of the stars being available.

Dr. Shapley, of Harvard Observatory, agreed that this work was of great importance and the late Miss Cannon undertook the responsibility for it. Unfortunately, the identification of the stars by their Right Ascension and Declination proved too laborious, but the method finally adopted was highly successful. The positions of the stars in a region of the sky photographed by Dr. Shapley having been calculated from rectangular co-ordinates, it was possible by means of the latter to identify the stars on the Astrographic plates by the réseau. It is highly creditable that the spectral types of nearly 90 per cent of the stars were determined and at the same time the spectral types of most of the outstanding stars of the Zone Catalogue. The latter appear as an appendix.

Altogether fifteen tables are given in the volume, and a full explanation accompanies each of these. Under Magnitudes, Table 1 compares the magnitudes in various catalogues with the Cape mean photographic magnitudes. The basis of the system for the "Cape Magnitudes" is explained at the beginning of this section. A sequence of 71 stars from mag. 5 to mag. 12 was selected in the neighbourhood of the South Pole, and an accurate photographic scale was established among these stars by means of a diffraction grating and a series of exposures ranging from 3 sec. to 30 min. The zero point of each plate was based on the Harvard visual magnitude of the brightest star, σ Octantis, mag. 5·48, corrected for the type *F*0. This scale was then transferred to twenty-four Astrographic Regions in declination −45°, each region being photographed on the same plate as the polar sequence.

Other sections, most of which contain one or more tables, deal with star counts, spectral types, mean colour index, faint stars of large proper motion, stars with large proper motion, motion of stars in general, the nearest stars, mean parallaxes. The Catalogue itself is preceded by a brief "Explanation", though the headings of the columns are generally sufficient to explain what follows.

* Catalogue of 20,554 Faint Stars in the Cape Astrographic Zone −40° to −52° for the Equinox of 1900·0 giving Positions, Precessions, Proper Motions and Photographic Magnitudes derived from Photographs taken at the Royal Observatory, Cape of Good Hope, under the direction of Dr. H. Spencer Jones and Dr. J. Jackson; also Spectral Types classified from Plates at the Harvard College Observatory, Cambridge, Mass., U.S.A., by Miss Annie J. Cannon. Pp. lvii+414. (London: H.M. Stationery Office, 1939.) 42*s*. net.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

THURSDAY, JULY 17

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. W. W. C. Topley, F.R.S.: "On the Biology of Epidemics (Croonian Lecture).

FRIDAY, JULY 18

INSTITUTE OF PHYSICS (MANCHESTER BRANCH) (in the Physics Department, University, Manchester), at 7 p.m.—Dr. H. Spencer Jones, F.R.S.: "The 200-inch Instrument".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEPUTY DIRECTOR OF EDUCATION—The Director of Education, County Hall, Chichester (July 18).

LECTURER IN MATHEMATICS—The Acting Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham, Essex (July 19).

HEAD OF THE SCHOOL OF PHARMACY—The Principal, College of Technology and Commerce, Leicester (July 21).

DEMONSTRATOR OF PHYSIOLOGY AND BIOCHEMISTRY—The School Secretary, St. Mary's Hospital Medical School, London, W.2 (July 26).

REPORTS AND OTHER PUBLICATIONS

(*not included in the monthly Books Supplement*)

ANGLO-AMERICAN COLLABORATION

IN a speech read on his behalf on December 11, Lord Lothian affirmed his belief that the only nucleus round which a stable, peaceful, democratic world could be built after this War was the possession by the United States and Great Britain of air-power, sea-power and key positions superior to those of any possible totalitarian rival. Peace and order always depend on the existence of an overwhelming power behind just law, and more and more people have come to the conclusion that all real hope depends on some form of co-operation between the United States and the British Commonwealth of Nations.

Without some such general realization and indeed actual co-operation, it is almost inconceivable that the British Ambassador in Washington could address the people of the United States so directly, however careful he might be, like Lord Lothian, to state the essential facts and to emphasize the responsibility of his hearers to decide for themselves. The events of the last six months have abundantly justified such frankness and demonstrated the recognition by the two peoples of their common danger and their solidarity in defence of the ideals and heritage which they share. Anglo-American co-operation has become a reality and a dominant factor in the war itself and in the peace and reconstruction to follow. The questions at issue are now those of the extent and form which such co-operation will take.

With the growing scale of America's contribution in the material sphere, there has been a notable contribution in the moral sphere. It is no disparagement of the speeches of Mr. Churchill, of Lord Halifax or of Mr. Eden to say that the major contributions in the statement of the moral issues of the War and its social, economic and spiritual objectives have latterly come from the American side. That might well be expected, but the warmth and sincerity with which they have been welcomed indicates how fully they are shared in Great Britain and how wide and firm is the foundation upon which practical measures of co-operation can be based.

Nor should it be imagined that this affinity of ideals and purpose is limited to leaders. The American Press affords decisive evidence that President Roosevelt, Mr. J. G. Winant and Mr. Wilkie are speaking for, as well as to, their countrymen. American periodicals such as *Fortune* leave their readers in no doubt as to the consequences which flow from the Lease-Lend Act. The probability of a direct collision with Germany is recognized, as well as the opportunity which the acceptance of that challenge would afford the United States to make the international view effective. The decision to fight for international

democracy would indeed not only be a decision to fight for a world in which there was still room for American ideals. It would also be the opportunity to build a new era in which the dualism which has hitherto characterized American foreign relations could be transcended.

Mr. Streit's new book "Union Now with Britain"* bears striking testimony to the startling transformation of American opinion and policy from the consistently isolationist attitude which characterized it during 1919–39. Written as it is primarily and essentially for Americans, it is this changed outlook, sensed or implied rather than directly described, which is the most striking feature of the book in contrast with "Union Now", overshadowing the fact that the intervening two years have witnessed the passage, one by one, under the Nazi heel, of eight of the fifteen democracies for the federation of which he pleaded in "Union Now". The successive fall of these democracies before the same tactics, has brought home to the United States not merely the fuller realization of the ideals and trust for safeguarding man's heritage of freedom which she shares with Great Britain, but also the clear understanding that the choice for her also is between standing now by Britain's side or fighting later and alone in a totalitarian world.

Ostensibly Mr. Streit's new book is concerned with the organization of co-operation, with the development of the most effective machinery for harnessing the resources of the United States and the six democracies of the British Empire to their common task. Fundamentally the book is vibrant with the moral conviction and ideals which have given such force to President Roosevelt's and Mr. J. G. Winant's speeches. The spirit and conviction on which his views are based are irresistible. No nation can live to itself alone. Each nation must give, and he calls on Americans to give fully and with open hands the best they have.

It is on this basis that Mr. Streit pleads for a union of the United States with the six democracies of the British Empire—the United Kingdom, Australia, Canada, Eire, New Zealand and the Union of South Africa—on the lines of the American federal system but with modifications which introduce something of the British parliamentary and Cabinet systems, and starting with a limited union. The working out of a broader and permanent union would be left until later, but the provisional union is intended and planned to be the nucleus of a world federal union to which each western European democracy would be admitted as soon as it is no longer occupied by the forces of dictatorship. Beyond that, the admission of such peoples as the Germans themselves is contemplated when, by ending autocracy at home, they have proved their devotion to democratic principles and their capacity to practise them.

Mr. Streit writes persuasively of the capacity of such a union to win the war as well as to win the peace. From the outset the Union would be prepared to negotiate armistice and peace terms with any Government attacking any territory of the Union on conditions of no indemnities, no reparations, occupations or annexations, and of arbitration of disputes on details. Such an announcement could be used to undermine the totalitarian regimes, encourage revolt and distrust among them and promote the downfall of dictatorship.

Writing eagerly with the moving quality of vivid talk, Mr. Streit rapidly outlines a union programme and discusses alternatives to such a policy. For what he has to say of Anglo-American co-operation there can only be the most cordial assent, and the basic proposal of the creation of a community of principles is inescapable. It is indeed implicit in such speeches as those of Mr. J. G. Winant's to the English-Speaking Union, with its insistence that the common ideals of the English-speaking peoples of this world are not ideals from which other peoples are excluded, on the drawing together of the English-speaking peoples in a struggle to preserve not only their common heritage but also the common ideals of civilized men everywhere, and its firm declaration that this is not Britain's fight alone. The ultimate stakes, the four freedoms of which President Roosevelt has spoken, are the foundation of their common effort, and that the time of action, the hour of decision, has arrived for all who love freedom can no longer be denied.

While the gap between political realities and the vision of Mr. Streit's "Union Now" has been greatly narrowed in the last two years, his argument is less conclusive as to the form which the organization of co-operation should take. It may be possible to demonstrate that had the union existed, the democracies included in Mr. Streit's earlier union would not have fallen. There is, however, no evidence that, even if made earlier and accepted, the offer of union which Great Britain made to France would have averted the fall of France. Federal union alone between Great Britain and France could scarcely have eliminated in time those weaknesses which led to the fall of France, though it might have ensured that the French fleet and French colonies continued the struggle.

On the other hand, as *Fortune* points out, the Lend-Lease Act really constitutes the first crude step in union. By its terms Great Britain and the United States pool such matters as military equipment, production, specification and design, hitherto strictly national. Moreover, the same pool is

* Union Now with Britain. By Clarence K. Streit. Pp. 286. (London: Jonathan Cape, Ltd., 1941.) 7s. 6d. net.

offered and made available to any other country that will take the side of democracy by standing up against Germany. This has been done, however, on the basis of friendship and engagement in a common venture, and that of itself may suggest that, as alternative to federal union, the British Commonwealth of Nations, united by common conventions and understandings about the position and the action of its members, not by virtue of common federal institutions, at least deserves consideration.

It is a mistake to insist too crudely that the choice is between federal union or a formal alliance, as Mr. Streit does, and to reject the latter as bad. It is at least possible that there is a third way, tentative and difficult, but in the end surer and wiser—the experimental way of finding and working out our common understandings and forging the appropriate instruments to serve common purposes. Already we have seen the chastening of nationalism in the British Commonwealth. Given the dynamic outlook and readiness to face change and try new methods, the consciousness of common ideals and traditions which lend Mr. Streit his own inspiration, the same spirit which has worked out effectively the relations between the United Kingdom and the Dominions may work no less harmoniously and effectively between the United States and the British Empire.

To that task must be addressed not idealism alone but also the dispassionate spirit of scientific inquiry, ever advancing step by step as new experiments in co-operation are tried. To such experiments the moral appeal and the rapidly developing world situation give urgency, but it is only on the basis of ascertained facts that Great Britain and the United States can discharge adequately their inescapable responsibilities in peace or in war for the defence of freedom and their common heritage. Whether the first or final stage be union, partnership in some more or less organized form will be required to resolve the conflict between nationalism and trade, industry and culture, and make possible a reconstruction of the world on principles which transcend the national sovereignty that has plunged it into chaos. In such a partnership Great Britain and the United States may well once more attest the truth of Lowell's prophetic words of February 1861, and their manhood make a greater opportunity out of the great danger which they at present share.

FACT AND TRUTH

FROM time to time there flare up echoes of the old controversy between science and religion; not, be it noted in any official form in the sense that leaders of either party take part, but individuals of deep convictions suddenly produce attacks, occasionally in print, which one had hoped were disposed of half a century ago. The fact that such attacks still occur is a reflection on men of science themselves, indicating that they have not yet succeeded in spreading the message of science so widely as they should have done; though it may be in part due to singular obtuseness on the part of their hearers.

The ill-informed have in recent months frequently blamed science for the misuse that has been made of its gifts to mankind, for the developments of the means of waging modern warfare. With that aspect we have often dealt, and we need not go over the ground again. A particularly subtle form of attack on science, however, is to take the line that the facts of science actually have the impermanence of matter, which changes and fades continually, and to contrast them with the truths of religion, which are permanent. Science being based on facts, and the facts relating to it mainly on matter, the argument is, on the face of it, worth examination.

The Oxford Dictionary gives a long definition of *fact*—"thing assumed as basis for inference"; "thing certainly known to have occurred or be true". *True* is defined there as "in accordance with fact". How do these definitions fit in with the outlook of the man of science?

There can be surely no question that the now vast body of scientific workers regard their observations as facts, and also they have a high moral sense of obligation for their pronouncements. As the result of carefully devised experiment, results are obtained which become a basis for inference. These are published for criticism by fellow workers, and if no flaws or omissions are found in the experimental work, they are accepted as facts and form the basis of theories—even of rival theories, a choice between which is only possible when further facts are available. Theories must be altered to fit facts; facts can never be adjusted to fit theories.

In more leisurely days, when a research was published after completion of the work, both facts and theories had been frequently tested during a year or more of investigation, and the final conclusions had a high degree of permanence. When work, however, such as that carried out in the Cavendish Laboratory, is of the greatest international interest, it is desirable to make the

results of the experiments known immediately, it being well understood by colleagues that additional work is in hand. In consequence, there has been a certain amount of correction and withdrawal—what some laymen have called impermanence of facts. This might perhaps have been avoided if publication had been withheld for two or three years, and only the final story told. But the loss would have far outweighed the gain; the individual laboratories would not have been aware of what the others were doing, which experiments to repeat critically, which further developments to pursue or leave to another laboratory. Quick publication has enormously accelerated the rate of progress; the withdrawal of a few errors has been a low price to pay.

Critics unfriendly to science say we 'assert': surely we have a right to do so. The orderly structure of chemistry, based on facts, has enabled us to prophecy with accuracy the existence as well as the chemical and physical properties of undiscovered elements. These were verified when the advancement in experimental technique made the discovery of a new element possible. It is true that the scheme of the elements as originally devised has been proved incomplete; for example, it made no provision for the group of rare gases, present in the air around us, discovered by Rayleigh and Ramsay: this is because for a long time the facts indicating their existence had been overlooked. But the fact—a minute difference in density between samples of nitrogen of different origin—once established, it was followed up until the reason for the difference was shown to be the presence in traces of another gas with very negative properties. Such facts have no impermanence, no relation to doctrinal system.

Another example may be quoted. The organic chemist had used facts to build up a molecular architecture, often of amazing complexity, for carbon compounds, including the natural substances of plants and animals. The chemist was convinced as to the accuracy of this architecture, for he had tested it in so many ways; but it was none the less satisfactory to have these structures confirmed when the Braggs, father and son, developed the technique of X-ray analysis. This, at first confirmatory, has now gone past what the chemist can do, and has established new facts so that we can picture the structure of starch and cellulose, hair and horn.

These are permanent facts, always being added to. The first theories are tentative; new facts strengthen or alter them, but they are always in a state of flux, for theories cannot be permanent though they may endure for a decade or many.

We cannot view the facts of science as impermanent. Doctrinal truths are in quite a different category; their discussion is an individual matter, and no part of our task.

A PHILOSOPHY OF PAIN AND FEAR

Fears may be Liars
By Prof. John A. Ryle. Pp. 96. (London: George Allen and Unwin, Ltd., 1941.) 3*s*. 6*d*. net.

PROF. RYLE's book has, he tells us, been written both for believers and unbelievers to hearten and console men and women in times of trial and trouble. He assures them that pain and fear are natural phenomena; that there is no evidence that they are punishments for our misdeeds: that on the contrary they are conditions not only of the survival but also of the advance of life—without them, it seems, the higher species could not have evolved—and that, so far from being shelved and shunned and enveloped in an atmosphere of mystery, they should be subjected to study and research which show them to be not so very dreadful after all.

Take death, for example. Religion, Prof. Ryle points out, has made death more formidable than it is, terrifying men with the fears of hell and bribing them with the dubious joys of heaven. In fact every death is the beginning of a "peaceful, dreamless night", a nothingness in which we cease to be. Prof. Ryle infers this view of death from the closeness of the mind-body relation. Sensations, emotions, feelings of pain and pleasure are all dependent on the integrity of the nervous system; at death the nervous system disintegrates and our sensational and emotional life, therefore, comes to an end. Possibly; possibly not! The question whether death is the end raises an immense variety of issues and can be approached from a multitude of angles. Of these issues, those that fall within the province of physiology are a small minority; of these angles, that of the medical man only one. For my part, I should have thought that the agnosticism of Socrates' argument—we do wrong to fear death, not because we know that nothing happens after it, but because we do not know whether what happens after (if anything) is better or worse than what happens to us when we are alive; it might just as well be better—was at once more prudent and less dogmatic.

Prof. Ryle proceeds to consider the possibility that it is not death but dying that men fear—death, as a wit remarked, would be all very well, were it not for the dying. But a little research shows that in the great majority of deaths, dying is a comparatively painless process, since coma or shock or hæmorrhage dims consciousness "with a dreaminess or delirium as effective as the precious gifts of the hypodermic needle" and dims, therefore, the consciousness of pain.

But it seems to me that it is not of death nor even of dying that most people are to-day afraid, but of disablement and pain—the being blinded, burnt, infected; the losing of a limb; the being tied for the rest of one's life to a broken and pain-engendering body. This increased sensibility to pain and disablement, this comparative indifference to death is, I suspect, a characteristic of civilized men and women. This is curious, since, as Prof. Ryle frequently observes, there have never been so many devices for the removal of pain; but it is not, I suggest, regrettable. It is a symptom of our demand for life at a higher level than that which sufficed our ancestors (a demand which for some of us has in part and on occasion been realized), a level which is incompatible with disablement or prolonged pain. It is not life *tout court* that we want, but life which can be lived out to the full scope and limit of our faculties. If we cannot have life at this freedom and of this intensity—and we cannot, if we are in continual and recurrent pain—many of us would sooner be without it altogether. I venture to make this point since it enables me to say why I find Prof. Ryle's apologia for pain unconvincing. It is grounded in the demonstration that pain is necessary for survival. If the broken leg did not heal, we should walk on it; if the inflamed tooth did not pain, we should bite on it and so on. In short, "if Nature, or God, had not invented pain, man could not have survived at all". Necessary for survival, pain is also useful for diagnosis. Hence we are bidden not to question Nature's foresight in announcing the presence of disease or "injury by pain".

I find this argument unconvincing. I do not know who or what Nature is, but either She or It has a purpose, or not. If She or It has no purpose, there is nothing and nobody to question. If, however, purpose is to be postulated, it seems to be simpler to go all the way with the religious hypothesis and postulate a Person who conceives the purpose and plans the world which is to fulfil it, in which case the phenomenon of pain assumes a different complexion and requires a different mode of treatment, revealing itself as a particular aspect of the moral problem of evil. Prof. Ryle is precluded from taking this line by his avowed rationalism. But, as a rationalist, what title has he to suppose that Nature or the universe takes any interest in us, benevolent or otherwise, that it *wishes* us to survive and has hit upon pain as a device for enabling us to do so? And why this insistence upon the importance of survival, on life at any cost and on any terms? Even if a man's life were abruptly terminated by accident or maltreatment which, owing to the absence of pain he failed to avoid, when, if he had been sensitive to pain he might have avoided it, why should it be assumed that his life was not worth while, more worth while, perhaps, than a life which was prolonged through pain and in pain? Why not in fact a short life and a painless one?

Prof. Ryle has some interesting things to tell us of fear (also diagnosed as performing a biological function in prompting defensive activity leading to survival) and of pain arising from his recent experiences in attending victims of air raids. The pains of even the worst hit victims are not, it appears, as bad as the layman would be led to suppose, for out of a convoy of twenty or thirty sufferers only two were heard by Prof. Ryle to groan. I am glad to hear it. But I cannot rid myself of the suspicion of occasional special pleading. Prof. Ryle is so determined to make the best of things that he never sees a cloud without looking for, and inevitably finding, the silver lining, with the result that when he means to be consoling, he too often succeeds in being merely complacent.

C. E. M. Joad.

INSECTS AND PLANT DISEASES

Insect Transmission of Plant Diseases
By Prof. Julian Gilbert Leach. (McGraw-Hill Publications in the Agricultural Sciences.) Pp. xviii+615. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 42*s*.

In 1801 it was shown for the first time that bacteria could cause plant disease, and this was only eleven years before the first scientific demonstration of a virus. The discovery that insects were concerned in the transmission of plant disease was made in 1901 when Takami showed that 'dwarf' or 'stunt' of rice was associated with a certain species of leaf-hopper, and at about the same time it was shown that insects could transmit diseases of man and other animals. As early as 1878 Manson had shown that mosquitoes were the

vectors of *Filaria bancrofti*, the nematode causing elephantiasis, and it was Manson, convinced of the importance of mosquitoes as vectors of disease, who stimulated and encouraged Ross in his studies on the transmission of malaria by mosquitoes. The importance of insects in the transmission of the diseases of man has led an increasingly large number of investigators into this field of research. These investigators are trained in the fundamentals of both entomology and medical science. The author of this book pleads for a similar training in the essentials of entomology and botany for potential workers in the field of insect-borne diseases of plants.

Diseases of plants and animals which are associated with insects and allied arthropods fall into a series beginning with that type of disorder which is not due to an agent multiplying within the host, but which is caused by the systemic distribution of a toxin injected by the insect or allied vector. In the plant world there are several examples of this type of disease, such as 'wilt' of pine-apples arising from a diffusible secretion incapable of reproduction injected by a species of mealy bug, and 'psyllid yellows', a disorder of a similar type caused by the potato psylla. This latter disease has all the appearances of a systemic virus disease except that it cannot be transmitted to other healthy potato plants and is not perpetuated by the tuber. A possible parallel in animals is tick paralysis, a condition due to the injection of a toxin by the dog tick. Next in the series come the virus diseases proper, in which an actual disease agent with tremendous powers of self-increase is concerned. In plants this type of disease is in particularly close association with insects and the number of insect-transmitted viruses is very large, curly-top of sugar beet and leaf-roll of potato being cases in point. There are also insect-transmitted viruses affecting man, yellow fever by the mosquito, for example.

The next type of disease is that due to the Rickettsiæ; these are extremely minute agents on the border-line of microscopical visibility which may perhaps be regarded as intermediate between the viruses and the bacteria since they have some characteristics of both. There are many rickettsia diseases of man and animals, the two best known being typhus and its milder cousin, trench fever, both of which are transmitted by the louse. Here also there seems to be a very close association between the disease agent and insects, and Zinsser has suggested that rickettsiæ were originally harmless parasites or symbionts in insects and that the pathogenic forms have developed from these. At all events there occur structures in the cells of many insects which resemble these agents and while no rickettsia diseases of plants are as yet known, similar structures can be demonstrated in phytophagous insects. This makes plain the importance of Chapter iii on insects and their symbionts, which otherwise might have seemed redundant. It is of interest to note in passing that the rickettsiæ of typhus fever become rapidly fatal to the louse itself which suggests that the association between the two is not complete and is of comparatively recent origin. Next in the list of insect-transmitted diseases are those due to undoubted organisms, bacteria, fungi and protozoa. So far as plants are concerned some of all three of these types of organisms are pathogenic and are transmitted by insects. The author himself has done valuable work on the bacterial disease of potato known as 'blackleg' and has shown the connexion between the causal organism and the dipterous maggot which transmits it. One of the most outstanding examples of an insect-transmitted fungus disease known to us is the so-called Dutch elm disease which is spread by the bark beetle, *Scolytus scolytus* Fabr. Examples of plant diseases caused by protozoa which are insect borne are not numerous, though flagellates which pass part of their life in hemipterous insects and part in laticiferous plants are well known.

Prof. Leach deals at length with all the foregoing types of insect-transmitted diseases and gives many examples of each. He devotes two chapters to plant viruses and their insect vectors and gives a comprehensive and up-to-date account of these. In addition to chapters on the actual diseases and the relationships of the transmitting insects, there is a great deal of valuable information on the fundamentals of the general problem. Thus Chapter xii deals with the anatomy and physiology of plants in relation to infection and insect vectors; Chapter xiii describes the anatomy and physiology of insects in relation to the transmission of plant diseases, while Chapter xv describes the feeding and breeding of insects from the same viewpoint. The author casts his net widely, but does so deliberately in furtherance of his plea that investigators in the field of insect-transmitted plant diseases should, like the medical entomologist, be trained in the fundamentals of both the subjects involved.

Prof. Leach is to be heartily congratulated on having brought together in a very readable form such a mass of useful information. There is very little to find fault with in this book, though the reviewer does not quite agree with the statement (p. 278) that "there are very few, if any, true virus diseases [of plants] that are not to some extent transmitted by insects". On the contrary, there are several undoubted viruses which apparently have no connexion with insects; such are the viruses of tomato bushy stunt, tobacco necrosis and potato paracrinkle and, in the reviewer's opinion,

tobacco mosaic virus also. Furthermore, there are about forty virus diseases which spread by unknown means, though no doubt insect vectors for some of these will eventually be found. Probably also the entomologist will not accept the classification of the Homoptera and the Hemiptera into two separate orders (p. 284).

The book is extremely well produced, and the illustrations are excellent. There are carefully selected references at the end of each chapter, and at the end of the book is an appendix giving many salient facts in tabular form. The price is rather high for the average student.

KENNETH M. SMITH.

ULTRA-LIGHT ALLOYS

The Technology of Magnesium and its Alloys
A translation from the German by the Technical Staffs of F. A. Hughes and Co. Ltd., and Magnesium Elektron, Ltd., of "Magnesium und seine Legierungen", compiled by Dr. Adolf Beck. Pp. xxiv+512. (Swinton, near Manchester: F. A. Hughes and Co. Ltd., 1940.) 30s. net.

THE great majority of the technically useful metals crystallize in the cubic system. There are, however, two important ones which have a hexagonal lattice, zinc and magnesium. Though neither of these has a history going back into the distant past, that of magnesium is much the shorter, the metal having been first isolated in 1808. This was about fifteen years before aluminium was isolated, but for various reasons the development of the latter was more rapid; and while aluminium had definitely established its place as an important industrial metal by about 1890, magnesium was only becoming a serious competitor in the neighbourhood of 1910.

The War of 1914–18 saw a great development in the uses of light metals, and the majority of the aluminium alloys at present in use were evolved during that period. Whether new magnesium alloys will be similarly developed during the present conflict remains to be seen: but there can be no doubt that an enormous increase in production must have taken place both in Great Britain and in Germany. This will be obvious to anyone who has been in the neighbourhood of a shower of incendiary bombs.

Many books have been written on aluminium, but apart from a small monograph published in 1937 by H.M. Stationery Office, the volume under review is the first which deals solely with magnesium and its alloys—the 'ultra-light alloys' as the French call them to distinguish them from the 'light alloys' of aluminium. The very marked effect of the anisotropic character imparted to the metal by its hexagonal lattice, and the great influence which this lattice has on the properties of the material, both in mono- and poly-crystalline forms, is very well brought out in the early chapters of the book. Indeed these chapters, dealing with the crystallography, metallography and physical properties of magnesium and its alloys, are probably the best. The one dealing with mechanical properties is very full of specific information, but is, nevertheless, scrappy, as it deals almost entirely with the alloys developed by the German firm with which the authors of the original book were connected—alloys which are, admittedly, the chief ones in use. The translators have had to re-write the first chapter on "Raw Materials" as in the original it presented a view of the situation which was completely biased in favour of Germany, and they have also added many valuable footnotes which help to correct the impression, undoubtedly given by the German edition, that no work has been done on magnesium alloys outside the Reich. The remaining chapters contain much that is of great value to the user of the alloys, whether he is engaged in forming the material into the desired shapes by casting, extruding, machining, etc., or in using the formed shapes in engineering construction.

It is almost certain that a new edition of this most valuable book will be called for some time, if only because of the progress in the subject that will undoubtedly be made during the War. When this is being written the following suggestions may possibly be of assistance. On p. 39 occurs the sentence "some alloys may be etched-down instead of polished". Apart from the ugly construction, the term "etched-down" is not a recognized one, and if it must be used it should be explained. On p. 61 the name Grime is spelled Grimme. On the same page reference is made to the work of Pusîn and Micîc. The authors, in the original paper, called themselves Pušin and Micić. The obvious misprints on pp. 119 and 144 would doubtless be corrected in the new edition. The definition of 'creep' on p. 198 appears very arbitrary and the omission of any reference to general corrosion on p. 273 should be rectified. Table 56 (p. 285) is not at all clear. Probably "pure Mg" should refer to test-piece No. 1 only. A more general point is the conversion of metric units into British ones. Is it necessary, or even advisable to do so, particularly in cases where material has been made to a definite

simple size expressed in centimetres or tested under a load expressed in simple integers when metric units are used ? For example, on p. 159 reference is made to alloys which were submitted to five different stresses of 0, 3·2, 6·3, 9·5 and 12·7 tons per square inch. One naturally wonders why these strange loads were chosen, until one realizes that the stresses actually applied were almost certainly 0, 5, 10, 15 and 20 kgm. per sq. mm.

Finally, but this time a really big request, could not Chapter v ("Mechanical Properties") be re-written on quite a different basis?

Reference has been made above to a new edition. Until this appears this handsome and useful volume is sure to be in constant use by the large number of people who are now so closely connected with ultra-light alloys.

JOHN L. HAUGHTON.

SPECTROSCOPIC METHODS OF ANALYSIS

The Spectrochemical Analysis of Metals and Alloys

By F. Twyman. Pp. viii+355. (London : Charles Griffin and Co., Ltd., 1941.) 21*s*. net.

MORE than a century has elapsed since Fox Talbot laid the foundations of chemical analysis with the spectroscope by his observation that lithia and strontia could be distinguished by optical analysis of their flame spectra. This original idea has proved so fertile that there are now few elements traces of which cannot be identified by their spectra. It is appropriate that Talbot, a notable pioneer in photography, should have initiated a technique which owes so much to the photographic plate. Indeed the development of spectroscopy and its widespread use in present-day industry would not have been possible without the photographic recording medium. Perhaps it is almost equally true that this expansion would not have occurred without the modern spectrograph with its twin virtues of optical excellence and simplicity of operation. Mr. Twyman's contributions to the design and production of such instruments are outstanding and none will question his authority to write a book on spectrochemical methods, more especially as he has maintained close contact with spectroscopists and their technique for more than forty years.

'Spectrochemical analysis' is a compound term which the author adopts in preference to alternatives, such as the ambiguous 'spectrum analysis'. It includes any method of determining the elemental constituents of a substance from its spectrum. The book begins with an excellent historical survey and an elementary account of atomic spectrum theory. Subsequent chapters on instruments and accessories include a very thorough treatment of the microphotometer, an instrument which is of considerable importance for the measurement of line densities on the spectrogram. The major part of the book deals with the quantitative determination of impurities and alloying constituents in metallic samples, but there is a single chapter devoted to analytical techniques for miscellaneous materials including solutions and gases.

It is shown that quantitative analyses can be made swiftly and to sufficient accuracy for a high proportion of metallurgical requirements such as the sorting of scrap, control of alloy compositions, and the checking of purity. The author claims that a minor constituent can be determined to an accuracy of between 2 and 7 per cent, provided certain conditions are fulfilled. Extensive accounts are given of the various techniques in use for the analysis of aluminium and ferrous alloys. Methods are also described for brasses and bronzes, precious metals, lead, magnesium and zinc alloys, and indeed for most of the common metals and alloy groups. The relative scope and merits of alternative methods are carefully assessed, and often their respective advantages have been combined in a standard technique used in the author's laboratory. Practical aspects such as mode of exciting the spectrum, electrode shape and pre-sparking time are treated fully, and in many instances suitable spectral lines for intensity measurement are listed. One slight inconsistency has been noted. Reference is made to the detection of as little as 0·001 per cent of tellurium in a copper globule arc ; this conforms to the reviewer's own experience. Yet twice in the earlier chapters it is indicated that tellurium is not excited in the arc.

References and quotations are abundant throughout the book. The majority of the quotations are usefully included, but a few of them are perhaps too lengthy and are not accompanied by sufficient critical comment for the reader's guidance. The illustrations are adequate, except for a complete absence of photographs of modern apparatus, possibly in view of the author's expressed intention of avoiding reference to the firm with which he is associated. The book is suitably indexed and a bibliography is included, which increases its value

as a work of reference. Units and definitions are also given in an appendix, and it is gratifying to see the logical notation for millimicrons, mμ, used instead of the incorrect $\mu\mu$.

All those engaged on spectrochemical analysis and especially metallurgists will be stimulated by reading Mr. Twyman's up-to-date account of other workers' methods, and they could usefully retain the book for permanent reference. There must also be many responsible for industrial processes who would discover in the method valuable applications to their own problems. The reviewer has not observed any important typographical errors and the quality of binding is well up to the peace time standard associated with the publishers.

L. A. THOMAS.

EPIDEMIOLOGY FOR THE MILLION

Plague on Us

By Geddes Smith. Pp. viii+365+10 plates. (New York: The Commonwealth Fund; London: Oxford University Press, 1941.) 16*s.* net.

THERE are few subjects which tempt 'experts' to write popular books so much as epidemiology; but it would be hard to name a single volume in English which has secured and maintained popularity. At first sight this seems odd; all men are interested in health and disease, the dramatic value of great epidemics is intense and the detective side of epidemiological investigation should appeal to the large reading public which reveres Dr. Thorndyke, Mr. Reginald Fortune and Lord Peter Wimsey. There are many reasons for the lack of success. The possession of a medical qualification, even clinical eminence, does not ensure expert knowledge of epidemiology, while professional *esprit de corps* and an urge to improve the occasion lead to a propagandist treatment. On the other hand, real 'experts' like Creighton (who also had the gift of literary style), *will* hunt hares of their own raising, and the rule Creighton adopted, namely, that whatever was believed by the majority of his medical contemporaries must be wrong, is quite as misleading as simple faith in the infallibility of 'doctors'. Finally, the subject-matter is so vast that an attempt to cover the whole field is threatened on one side by dullness and on the other by sciolism.

Now, when many thousands of men and women are doomed to die of epidemic diseases directly or indirectly due to war, a new appeal to the interest of the many in disease is timely. Dr. Geddes Smith devotes his first chapter to brief but dramatic accounts of great epidemics, or incidents in great epidemics, of the past. To the English reader it is both instructive and interesting that here and in other parts of the book examples are so far as possible drawn from American experience. We tend to be too insular in our epidemiological teaching, and to forget that American epidemiological records cover a much wider field than our own. There follows an excellent account of epidemiological doctrines from the time of Hippocrates to our own days. The next chapter is mainly concerned with the individual biology of infection, the reactions of host and parasite, but the herd aspects as elucidated by Topley, Webster and their respective colleagues are carefully explained, and, in the following chapter, the herd aspects are fully discussed. The next chapter, on defences, necessarily follows beaten tracks, but is refreshingly free from professional dogmatism and over-statement. The following chapter, "Detective Work", tempts me to break the Tenth Commandment; the "Case of the Methodist Ladies" or the "Case of the Sleepy Lobsters" read to schoolboys might do much to awake interest in hygiene. The last chapter, "Unfinished Business", is concerned with the unsolved problems of epidemiology—certainly not less important than those solved. As the author remarks in an epilogue, "The diseases stopped in their tracks by the use of vaccines or antisera are few, and those still unpreventable by such means are many."

In any book covering so wide a field, any specialist will find statements with which he does not agree. The natural predilection of a cobbler for leather inclines me to regret that rather more emphasis has not been put on the importance of the pioneer work of Graunt, Petty and Halley in deflecting interest from speculative opinion to measurable fact. The work of Louis, mentioned in the footnote on p. 55, was directed to show the value of statistical methods in *clinical* research, and, unfortunately, had little effect in Europe. I should have welcomed a critical survey of American developments in this field, particularly as Raymond Pearl and his pupils did much to arouse interest in the analysis of hospital data. But these are matters of secondary importance, and perhaps of little interest to the million. Taken as a whole, this seems to me the best book I have read on the subject, and should do much to raise the level of epidemiological discussion, not only in general, but also in professional circles.

MAJOR GREENWOOD.

An Introduction to the Practice of Organic Chemistry in the Laboratory

By Prof. Homer Adkins, Prof. S. M. McElwain and Prof. M. W. Klein. (International Chemical Series.) Third Edition. Pp. ix+294. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 17*s*. 6*d*.

IN this introduction to the study of organic chemistry, an attempt is made to interest the student in the general principles underlying the experimental work involved in the preparation of fifty carefully chosen compounds by devoting the greater part of the work to the discussion of such general reactions as oxidations and reductions, esterifications and hydrolysis, halogenation, nitration and sulphonation, diazotization, intra-molecular re-arrangements and special reactions including some modern work, and inserting cross-references to the relevant paragraphs to these discussions in the directions for procedure. Relatively little attention is given to qualitative and quantitative analysis, but a few physico-chemical topics such as those involved in the distillation of azeotropic and other mixtures and in extractions with solvents are discussed.

Rules are given for the proper use of note-books, and, since equations and formulæ are deliberately omitted from the experimental directions, the student is expected to make a careful study of each experiment by reference to text-books and to the discussions before beginning the work. At a later stage he is expected to undertake problems involving the use of the library, and a very welcome feature of the book is a chapter devoted to the use of the literature. Some experiments suitable for senior students are included, with references to original memoirs and to standard works of reference. One or two misprints have been noticed and also several mistakes in structural formulæ, but apart from these minor defects the book is likely to stimulate the interest of the novice in organic chemistry.

The Scientific Photographer

By Dr. A. S. C. Lawrence. Pp. x+180+5 plates. (Cambridge: At the University Press, 1941.) 18*s*. net.

IN the preface the author puts in a plea for the more frequent use of photography in the laboratory for the making of permanent records of apparatus and experiments, and for the more extensive use of the lantern slide and cine film for teaching and demonstration purposes. This book is written primarily for the scientific worker who wishes to make use of photography either to augment his own research records or to illustrate his published work; but it is also directed to the serious amateur photographer who, however skilled he may have become by experience, can only benefit by a knowledge of the fundamental principles of photography.

The physicist may find some sections elementary, and in one or two places statements may be found that will scarcely satisfy him. For example, one finds it recorded that the brightness range obtainable in a transparency is greater than that in a print because "the amount of light passing through the high-lights [of the transparency] may be increased at will by increasing the power of the light source".

The book is easy to read and well illustrated, and a great deal has been condensed into its pages. In attempting to cover such a wide field some subjects have inevitably received brief treatment, but the book provides a good groundwork for the thoughtful reader and should give the scientific worker all the information he requires to carry out any normal photographic operations.

Differential and Integral Calculus

By Prof. Ross R. Middlemiss. Pp. x+416. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 17*s*. 6*d*.

THE author of this useful volume touches a vital spot when he says that "while in a first course many students acquire some facility in manipulating calculus symbols, very few obtain a real understanding of the fundamental ideas of the subject". The text has therefore been prepared in order to present the principles and processes of the calculus with special clarity and simplicity without sacrificing accuracy, and there is no doubt that the author has carried out his aim with skill and thoroughness.

Of the twenty-eight chapters, the first thirteen are devoted to functions and their graphs, limits and derivatives. Integration, as the inverse problem of differentiation, then follows and covers the standard forms with many well-chosen practical illustrative examples. The succeeding chapters deal with Duhamel's principle, mean value theorems, centroids, moments of inertia, centres of pressure, partial derivatives, multiple integrals, series, expansion and elementary differential equations. At the end of the text, a handy table of integrals is provided, for reference, together with tables of logarithms, common and Napierian, trigonometric functions, powers, roots, exponential and hyperbolic functions. Large numbers of exercises, with answers, are supplied, which are both interesting and instructive. The text is excellently printed and well illustrated by clear diagrams and isometric drawings. No student who conscientiously works through the course should have any difficulty in reaching a full understanding of the basic principles of the calculus.

Les Chaleurs spécifiques

Par Prof. Edmond Brun. (Collection Armand Colin: Section de physique, No. 224.) Pp. 224. (Paris: Armand Colin, 1940.) 15 francs.

SOME of the books of this series on physical subjects have justly attained an importance out of all proportion to their size. The present volume definitely belongs to this category, for it gives a most admirable survey of the whole field, experimental and theoretical, of specific heat measurements. It is very clearly written, and, as an example, one may mention that a chapter of some twenty-five pages on specific heat anomalies in solids is remarkable for a concise non-mathematical account of order-disorder transformations in metals and alloys. Most students will find it an excellent guide to the study of specific heats.

L. F. B.

FOOD PRODUCTION BY FISH AND OYSTER FARMING

By Dr. F. Gross,
Department of Zoology, University of Edinburgh

History

FISH culture experiments with marine fishes have been made in the past along two lines: (1) Eggs of cod, plaice, turbot and sole have been hatched in hatcheries and the larvæ, prior to the complete absorption of yolk, returned to the sea. In a series of such experiments undertaken by Dannevig for the Scottish Fishery Board, the larvæ were transported to Loch Fyne and released there. (2) Young plaice have been transferred from crowded inshore grounds to richer feeding grounds which were hitherto sparsely populated by plaice.

Hatching operations were undertaken on a large scale in the United States, Norway, Scotland and the Isle of Man, and many millions of larvæ were liberated each year. The results have been much disputed and the statistical data are rather scarce. Fulton[1], discussing the Loch Fyne experiments, came to the conclusion that the liberation of 142,880,000 fry of plaice led to a substantial increase of the plaice population. During the period 1896–1901 when the fry were transferred to Loch Fyne, the average number of young plaice taken with a push net at various points of the Loch was 87·7 per hour, whereas in the second period (1903–1908) when no plaice fry were added, the average number taken per hour was 39·7, or less than half.

The transplantation of young plaice from Danish and Dutch coasts to the Dogger Bank[2,3] in the years 1904–1908 was followed by a remarkable growth of the fishes. The average initial size of the fish transplanted was about 8·75 in.; the average length of the plaice recaptured one year after liberation was 14 in., an increase of 5·25 in. Had they remained on the inshore grounds from which they were taken the annual growth would have been only 2 in. The average growth in weight of the transplanted fish was even more striking, amounting to 382 per cent of the original weight. Similar fish on the inshore grounds only increased their weight by 100 per cent in a year. It is important that, though the growth of the transplanted fish took place most rapidly in the summer months, a certain amount of growth did take place even in winter, when growth on the inshore grounds practically ceases.

Since 1908 the Danes have been transplanting 1–3 millions of plaice annually to the Inner Limfjord. The growth of the transplanted fishes, measuring 16·3–19·1 cm. in length, was very rapid. During one growth period, from April until November, it amounted to 8–13 cm., so that in the autumn most of the transplanted fish weighed about 375 gm. as against an average weight of about 57 gm. on liberation. These figures are taken from Blegvad's report[4] which also summarizes the results of the large Danish experimental transplantation of North Sea plaice to the Belt Sea in 1928–1933. The transplanted fishes showed an increase of 10–12 cm. in length, and 120–490 gm. in weight during the first growth period, which is nearly twice the growth of the local Belt Sea fish. A calculation relating to the transplanted fish of the year 1931 gives the total value of the fish recaptured as amounting to 120,000 Kr., while the actual cost of the transplantation is put at about 40,000 Kr.

Marine Food Resources in War-time

In view of the present difficult food position it would seem desirable to inquire into the possibilities of utilizing to a greater extent the food resources of the sea. For obvious reasons the activity of fishermen is greatly restricted in war-time, the supply of fish is relatively small and the price of this valuable food high. Could we look to an extended practice of fish culture for an increase of the supply of fish? There is no doubt that in areas of water under proper control the culture of freshwater fishes has proved highly profitable. In 1915 Allen[5] compared the yield of organic substance derived from a given area of fresh water, sea water and land, and his figures may be quoted here:

Continental carp pond:	95	lb. of fish per acre per year
Enclosed harbour:	89	,, ,, ,, ,, ,, ,, ,,
Cultivated land:	73	,, ,, beef ,, ,, ,, ,,
Fish from the North Sea:	15	,, ,, fish ,, ,, ,, ,,

Allen then remarked: "The extension of fish culture to marine fishes, which are much more delicate and difficult to rear than those which live in fresh water, is by no means an easy matter, and much further knowledge will be necessary before successful results can be obtained."

Since the time when the various hatcheries began their operations, our knowledge of the sea and of life in the sea, of the life-histories of marine organisms and the conditions governing their growth, has been greatly increased, and a new attempt at the culture of marine fishes would be justified. To succeed in such an attempt marine biologists will have to take counsel of the fresh-water farmer. The large crop taken from a carp pond was the outcome of the application of two sound and simple agricultural principles: (a) an area of land can support a larger population of plants if the soil is properly manured; and (b) if a herd of animals is to be maintained on a piece of land that does not fully provide all the food required by the animals, the diet must be supplemented by some extra feeding-stuff. True to these principles the carp ponds receive a copious supply of stable manure drained direct into the pond, and fish meal is added to supplement the food provided by the intensive growth of the vegetation and the fauna of the pond as a result of the manuring.

The marine hatcheries which have returned to the sea millions of fish fry in a most helpless and delicate stage have, in a way, attempted to get something for nothing. They expected a richer harvest merely by increasing the number of seeds sown. It is true that the protection afforded during their embryonic development and part of their larval life may result in the survival of a number of larvæ liberated. But this number cannot be substantial; there is no food for a surplus population of larvæ belonging to an indigenous species. As it takes roughly six million eggs to give two turbot a chance of reaching maturity, it is probable that the release into the sea of the larvæ will also result in the destruction of the vast majority owing to the severe competition under natural conditions.

The liberation of large numbers of larvæ in Loch Fyne was a hazard. As it turned out, the experiment was successful to a degree, leading to a certain increase of the plaice population. It was a hazardous undertaking as, so far as I know, no survey of the plankton and the bottom fauna on which the plaice depend for food had been made prior to the 'planting' of the larvæ. Loch Fyne had a plaice population of its own which naturally did its best to grow in numbers. As no steps had been taken to increase the food supply for the greatly increased larval population, only a mere fraction of the 142,000,000 fry was given a chance to survive.

It is common knowledge that animal life in the sea depends to a large extent on the phytoplankton for its supply of organic food, and it seems obvious that the bulk of animals maintained is roughly proportional to the bulk of the vegetation on which they directly or indirectly graze. It is significant that Allen, in the address referred to, said that his work on the artificial culture of plankton diatoms was commenced "largely with a view to obtaining information about some of the fundamental problems upon which any scientific practice of fish culture would need to be based". Further work has brought a fuller understanding of the different factors favouring and limiting the growth of phytoplankton in the sea.

Cultures of quite a number of species of plankton diatoms and autotrophic flagellates can be maintained in the laboratory throughout the year [6,7], each subculture reaching a density of population many times greater than in the sea. During the spring outburst the number of diatom cells may reach a maximum of about 50,000 per litre in the sea[8]. In Loch Striven as many as 25,000,000 cells per litre are present for a short period during the spring increase[9]. In a culture, 500,000,000 cells per litre may be reared at all seasons, provided the culture medium is properly enriched with nutrients required for their growth, namely nitrate, phosphate and soil extract, containing substances the action of which, though not yet fully understood, is highly beneficial for the growth of marine organisms.

Attempts to culture plankton organisms on a larger scale in the 'plankton shaft' of the Oceanographic Institute in Göteborg gave encouraging results[10,11]. In spite of the detrimental effect of convection currents, by which large numbers of diatoms were carried to the cooling pipes and immobilized there, the phytoplankton reached a population density larger than in the sea during the spring increase, namely, 660,000 diatom cells and many more autotrophic nannoplankton flagellates per litre. In a separate experiment, the density of the zooplankton population, consisting chiefly of copepods, that could be supported in the plankton shaft for more than three weeks was at least of the same order of magnitude as that occurring in the sea. Had it not been for some technical faults of the shaft it would probably have been considerably larger, particularly if diatoms as well as flagellates had been provided as food for the copepods.

We may now make certain proposals regarding the methods for the future culturing of marine fishes and oysters. It is essential that areas of water be chosen which can be to some extent controlled, that is, manured and stocked, if necessary, with organisms forming the food chain on which the fishes depend. Only artificial ponds, harbours and lochs connected with the sea by a mouth sufficiently narrow to prevent a rapid mixing of the water with the sea outside could be used for the purposes outlined below, and only

those fishes which show little tendency towards migration before maturity, for example, dab, plaice, turbot, sole and flounder, could be thus 'farmed'.

(1) FATTENING OF SMALL FLAT FISHES

It would be relatively easy to collect large numbers of flat fishes below marketable size, say 5 in., and transplant them into the chosen area which, analogous to the carp pond, would provide the conditions for rapid growth. The water would be manured with nitrate and phosphate, which, as we know, represent two of those 'limiting factors' that control the seasonal waxing and waning of the phytoplankton population. Other substances which are present in the sea in small exhaustible quantities and are required by the micro-vegetation would be provided by slow-acting fish meal manure and farmyard manure, if available, and by soil drained into the water. Thus the conditions would be created for a rich and prolonged production of phytoplankton. We cannot predict what kinds of organisms would respond best to the conditions provided; but there are probably few, if any, kinds that would not be utilized either as larval food or as food of the bottom fauna.

The great bulk of planktonic forms, and also the sedentary polychætes and lamellibranchs which form the chief items of the diet of flat fishes, are particle feeders, and are not very particular as to the kind of autotrophic organisms they filter into their digestive system. *Calanus finmarchicus*, for example, can utilize quite a range of organisms, from the most minute flagellates (2μ in length) to relatively large diatoms such as *Ditylum Brightwelli* reaching a size of 80μ by 100μ [12]. On the other hand, detritus should be a good source of food supply for the bottom fauna from whatever kind of phytoplankton it may have originated.

We may assume that under such conditions the local population of bivalves and polychætes would thrive and increase. If necessary, the stock could be augmented by the transplantation of large numbers of molluscs and polychætes from the sea-shore, and thus an ample food supply provided for a large fish population all the year round. The conditions for the growth of the fishes would then be at least as favourable as on the Dogger Bank or in the Limfjord, and the rate of their growth at least as high. That would mean that transplanted fishes of 120 gm. should reach marketable size—1 lb. in weight—in one year or even less. An annual increase in weight of 400 per cent may well be expected in view of Ben Dawes's investigations on the growth and maintenance of plaice[13] in which increases in weight of fishes ranging from 340 to 580 per cent and more were obtained during a period of 175 days.

(2) REARING OF FLAT FISHES

It was realized by Dannevig[14] that the advantage of fish culture would be much greater if the protection given to the eggs by the hatcheries during the embryonic development could be extended through the period of post-larval development until the time the flat fish lives on the bottom. The hatcheries did not rear the larvæ beyond the stage of yolk absorption because of the 'critical period', that is, one of very high death-rate, following that stage.

However, Dannevig was able to rear a small number of plaice without very much trouble, and a few specimens reached an average size of 3·25 in. in about nine months. Preliminary experiments with eggs of plaice, undertaken recently by me in collaboration with Mr. J. Raymont, show that after the absorption of the yolk the larvæ fed very actively on diatoms for about a week, and the death-rate during this period is negligible. In these experiments the stage after the complete absorption of the yolk was 'critical' and this only because the next link in the food chain, namely, crustacean or mollusc larvæ, could not then be provided. Rollefsen[15] reports in a preliminary communication that artificially hatched plaice and flounder fry could be successfully reared up to the bottom stage on a large scale by feeding with nauplii of Artemia. In our experiments the plaice larvæ did not take to feeding on Artemia nauplii, possibly because of their relatively large size* and attempts will be made in future experiments to bridge over the gap with small harpacticoids and cyclopoids which, like Artemia, are being cultured on a large scale in this Department.

Dannevig was probably justified in arguing that as rearing on a small scale is possible, it would be easier to rear larval fish in a large enclosure. "The success of such an experiment would mean that such valuable fishes as the sole and turbot could be protected in captivity throughout the time of the early development while the enormous destruction takes place in the sea."

However, even when planted out or kept on in enclosures after metamorphosis, great destruction would take place among the flat fishes, chiefly by cannibalism, and the growth of the fish would be very slow, unless the natural food supply of the area was increased. Growth depends on the

* The stock used for our cultures originated from an Italian polyploid parthenogenetic race[16].

density of the stock; great density entails less food per fish and therefore slower growth. If, however, the rearing of the larvæ were done in enclosures farmed in the proper manner, one might expect survival and rapid growth of a large proportion of small fishes, which after two years' intensive feeding might reach marketable size.

(3) OYSTER CULTURE

Recent experiments by Cole[17] in Conway and by Bruce, Knight and Parke[18] in Port Erin, show that by employing the culture methods for phytoplankton organisms, developed by me some years ago in Plymouth, and by feeding oyster larvæ with some of my cultures of minute flagellates a large settlement of oyster larvæ can be obtained. The procedure adopted in Conway is to let the larvæ settle on tiles placed in tanks and to transplant them afterwards to cages planted in the Menai Straits where growth takes place at a very satisfactory rate.

It is suggested that this work be extended by transplanting the settled spat to enclosed areas of water with a larger food supply than is available under natural conditions. The method may be further modified by allowing the larvæ to settle on pieces of rope and either to attach the ropes to poles stuck in shallow parts of the enclosure, as has been the practice of some oyster breeders in France and Yugoslavia, or to suspend the ropes on rafts floating at the surface.

These three types of experiments, quite apart from their economic potentialities, should yield results of great scientific interest. They would give us the first indications of the reaction of a large, but relatively isolated marine community to environmental changes brought about purposely by man; they would show how the intricate network of factors responsible for such phenomena as the seasonal sequence of plant and animal associations, their growth and decline, and the competition among the various species, would alter in quality and intensity under the impact of an 'agricultural' improvement of their ecological realm.

As to the localities where such experiments could be undertaken, their choice will depend largely on the scale on which they are to be attempted. I have consulted Mr. Elmhirst, Dr. Marshall and Dr. Orr of the Marine Station in Millport on this point and have discussed the whole scheme with them, receiving much encouragement from them. There are quite a number of lochs in Scotland which might be very suitable for pisciculture. Some lochs would probably require the damming up of their sea entrances, while, on the other hand, others could be farmed without damming.

To test the validity of the methods outlined above a preliminary investigation would seem desirable. For this purpose Loch Sween is perhaps suited best owing to the existence of three or more basins with entrances only 4–10 yards in width, which could be easily dammed up and used for the fattening and rearing of fishes and oysters. Dr. Orr informed me that the sand there, although muddier than in the open Clyde area, is probably quite suitable for young plaice. There are very numerous lug-worm casts, and mussels and cockles are abundant. In the branch of the loch called Linne Mhurich there are numerous shells of large oysters and Dr. Orr was told that there were still some oysters lifted each year in this branch. It therefore would be highly suitable for oyster culture.

Should the preliminary experiment prove successful, fish and oyster farming could be developed on a sufficiently large basis to add considerably to Great Britain's home-grown food supply. However, at present, the problem is to find the means for financing the preliminary experiments. A rough estimate made with the kind help of Prof. J. Ritchie puts the expenditure at about £3,000 for damming, compensation to owners, catching and transportation of young fish, etc. On the other hand at least 120,000 young fish would be transplanted for fattening, weighing approximately ¼ lb. each. A catch of 60,000 fish of 1 lb. at 1*s*. per lb. after one year would repay expenditure, of which the biggest items (damming and compensation) would not recur in the following year. Admittedly no such experiments have been made so far, and there is a certain risk that the project might not be altogether profitable as a commercial undertaking. This much can however be said: we have sufficient experience—from transplantations and culture experiments in particular—to plan it with a reasonably good chance of success.

ABSORPTION SPECTRA OF HÆMOGLOBIN IN SOLUTION AND IN RED BLOOD CORPUSCLES

By Prof. D. Keilin, F.R.S., and Dr. E. F. Hartree
Molteno Institute, University of Cambridge

IN 1877 and 1879 Hoppe-Seyler[1,2] put forward the theory that the hæmoglobin within the red blood corpuscles is not identical with that which appears in solution after lysis of the corpuscles. He even proposed for the intracorpuscular states of the pigments in arteries and veins the names 'arterin' and 'phlebin', reserving the names oxyhæmoglobin and hæmoglobin for the corresponding pigments in solution. However, the numerous arguments brought forward by him in support of this theory were soon invalidated by other workers, who found an easy explanation of all his observations without postulating the above theory[3]. Hoppe-Seyler's theory was soon abandoned, and considered until recently as of purely historical interest. It was, however, recently revived in a slightly different form with fresh evidence in support of it.

It is well known, since the classical work of Soret, that the absorption spectra of hæmoglobin and all its derivatives down to the porphyrin show, in addition to the absorption bands in the visible region, a strong and sharp band near the violet end of the spectrum between 405 mμ and 430 mμ. This band, which is much stronger than the other bands of these pigments, is known as the Soret band or γ-band. It is absent in all derivatives with an open pyrrol chain such as bile pigments or even compounds like verdohæmochromogen with an open tetrapyrrolic chain maintained in ring form by the central iron atom[4].

It was shown recently by Macallum and Bradley[5] (1930) and Adams, Bradley and Macallum[6] that the γ-band is absent in oxyhæmoglobin of intact corpuscles although it appears at once on hæmolysis. This observation seems to suggest that there must be some physical or chemical difference between hæmoglobin inside and outside red blood corpuscles. The problem was reinvestigated by Adams[7], who made an attempt to determine the nature of intracorpuscular hæmoglobin which could account for the disappearance of the γ-band. The main conclusion of his study is that within the corpuscle hæmoglobin is not free but forms with the 'stromatin' of the corpuscle a compound devoid of band γ. This compound appears to be very labile and rapidly dissociates, even on ordinary lysis, liberating the hæmoglobin which shows the normal band γ. This view is based on experiments *in vitro* which seem to show that hæmoglobin, when mixed with a solution of stromatin, brought to *p*H 9·7 and warmed for about 1hr. at 37° C., gradually loses its absorption band γ. It cannot be disputed that the problem as to the state of hæmoglobin within the corpuscles is of great physiological and biochemical interest. It is therefore a matter for some surprise that this phenomenon of obliteration of the γ-band discovered in 1930 has not stimulated more work in other laboratories. We should like to mention that although a quartz spectrograph as was used by the above workers is the best instrument for the quantitative study of this problem, the main optical phenomena can be observed and studied by means of much simpler spectroscopic apparatus more easily accessible to less specialized laboratories. We shall briefly describe the three spectroscopic methods used by us.

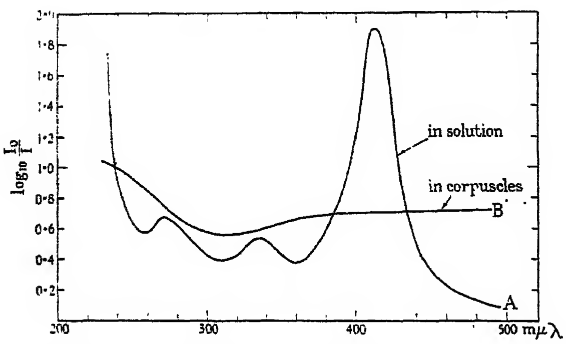
(1) Spectrophotometric method using Hilger quartz Spekker photometer.

(2) Fluorescent method. For this purpose light from 500 c.p. Pointolite lamp is focused on the slit of an ordinary constant deviation spectroscope. The eye-piece of the latter is removed and the emergent spectrum focused by means of lenses on to a glass cell (2 mm. thick) containing a fluorescent solution such as (*a*) 1 per cent solution of 3 : 6-dihydroxyphthalonitrile in 70 per cent alcohol and 0·2 per cent sodium carbonate, or (*b*) 1 per cent solution of 7-aminoquinaldine, in 70 per cent alcohol containing 0·1 per cent sulphuric acid. Using glass throughout, the spectrum extended down to about 360 mμ. The cells containing the absorbing solutions are placed between the spectroscope and the fluorescent cell.

Replacing the Pointolite by a mercury-vapour lamp enabled the apparatus to be calibrated. The drum of the spectroscope was set at 435·8 mμ and a pointer attached to the fluorescent screen to mark the position of the corresponding emission band. The wave-length of the absorption bands could then be determined by bringing them to the position marked by the pointer and reading the drum.

(3) The third method, which is the direct spectroscopic observation of the γ-band, is possible only for CO-hæmoglobin and desoxygenated hæmoglobin, the γ-bands of which are at 420 mμ and 430 mμ respectively. These two bands can easily

be observed with an ordinary microspectroscope ocular attached to a microscope and a strong light passing through a suitable filter such as copper sulphate solution combined with either a solution of ammoniacal copper sulphate or a Wratten filter *D*. This method, owing to its simplicity, was finally adopted for rapid spectroscopic examinations of hæmoglobin in red blood corpuscles and in solution. For this purpose 2 ml. of a dilute suspension of washed blood corpuscle in isotonic saline is placed in a Thunberg tube, and 0·2 ml. of a dilute solution of saponin is put into its hollow stopper. The tube is either evacuated and filled with carbon monoxide or boiled in a vacuum until the oxyhæmoglobin becomes completely desoxygenated. The content of the tube is then examined spectroscopically in a strong beam of



Absorption spectra of oxyhæmoglobin in solution and in corpuscles using Spekker U.V. photometer.

Curve A, 1 part washed blood cells in 2,500 parts water. Water in compensating cell.

Curve B, 1 part washed blood cells laked in 2,500 parts normal saline. Compensating cell contains a suspension of yeast in saline of approximately equal turbidity. The yeast suspension was matched nephelometrically in red light with the corpuscle suspension.

The values of the absorption coefficient are not absolute but are the readings obtained directly from the photographic plate using 20 mm. cells.

light passing through the coloured filters. Neither CO-hæmoglobin nor reduced hæmoglobin show any indication of the band γ before laking. On mixing the contents of the tube and the stopper the corpuscles are laked and the CO- or reduced hæmoglobin passes into solution.

Spectroscopic examination of the solution now reveals a very strong γ-band lying at 420 mμ or 430 mμ respectively. Similar results were obtained in experiments carried out by the first two methods. The second method, although comparatively simple and not requiring expensive instruments, enables the direct observation of the bands to be carried out much farther into the short wave end of the spectrum, which makes possible the study of all derivatives of hæmoglobin. The first method has the advantages of being quantitative and giving a permanent record of the experiment (see accompanying graph).

While reduced, oxygenated and carbon monoxide hæmoglobin are easily obtained within intact corpuscles, their conversion into methæmoglobin requires somewhat more complicated manipulations. The method adopted was as follows: 20 ml. corpuscles in saline are shaken with 20 ml. 1·06 per cent sodium nitrite in a 200 ml. centrifuge tube. After 5 minutes the tube is filled with 0·9 per cent sodium chloride, well mixed and centrifuged. The residue is then washed three times with normal saline. The methæmoglobin in the corpuscles can easily be transformed into the acid form by suspending them in 0·154 *M* KH_2PO_4.

All these experiments confirm and extend the results obtained by previous workers[6], namely that the very strong Soret or γ-band in the absorption spectrum of Hb, O_2Hb, COHb or metHb in solutions is scarcely perceptible or completely invisible in these pigments within the intact corpuscles.

We have also attempted to repeat the experiments to which we have previously referred and which according to Adams seem to prove the formation of a compound between hæmoglobin and stromatin.

For this purpose stromatin was prepared by two methods, that of Jorpes[8] and a somewhat simpler method which we have previously used for the purification of hæmoglobin[9]. According to this latter method 300 ml. of fresh horse blood corpuscles are cooled to 0°C. and laked with 90 ml. of cold distilled water and 90 ml. of cold pure ether. The mixture is shaken for five minutes, mixed with 30 gm. sodium chloride and centrifuged. The centrifuge tube contains two distinct layers, a thick almost solid layer of red stroma on the top and a clear, strong solution of hæmoglobin underneath. The centrifuge tube is slightly tilted, so that the clear hæmoglobin solution can be sucked off. The stroma are mixed with ice-cold water, thoroughly shaken, and centrifuged. This manipulation is repeated several times until most of the hæmoglobin is washed out.

Numerous attempts to combine hæmoglobin with stromatin, carried out under different conditions including those described by Adams, failed, however, to reveal any evidence for the existence of such a compound.

In all our experiments the γ-band of hæmoglobin remained strong and clearly visible, which is not surprising considering that this band belongs to all hæmoglobin derivatives containing a closed tetrapyrrolic ring. In fact it is present in porphyrin, hæmatin, hæmochromogen, parahæmatin, hæmoglobin, O_2Hb, COHb, metHb

and the compounds of the latter with H_2S, H_2O_2, NaN_3, NaF and NO.

In other words, even if the existence of the supposed hæmoglobin-stromatin compound is accepted, it could scarcely be expected that the absorption spectrum of such a compound would be devoid of the γ-band.

The absence of the γ-band in the suspension of intact red blood corpuscles, while it is present in a suspension of oxyhæmoglobin crystals or in an amorphous precipitate of hæmoglobin, excludes any simple optical explanation of this phenomenon.

Attempts were made to imitate a suspension of corpuscles by suspending droplets of concentrated oxyhæmoglobin solution in oil. For this purpose 0·1 c.c. of strong oxyhæmoglobin solution (containing 0·3 mgm. Fe per ml.) is shaken with 50 c.c. medicinal paraffin containing 0·02 per cent sulphonated castor oil. The mixture forms a permanent suspension of very fine droplets of hæmoglobin solution varying from 7μ to 14μ in diameter. Spectroscopic examination of this suspension shows that while the strength of the bands α and β is at least 80 per cent of that of the original solution, the band γ is completely invisible. A suspension in pure castor oil has similar properties. On centrifuging the suspension with a little water, about 75 per cent of unmodified hæmoglobin can be recovered. On the other hand, if oil droplets are dispersed in a dilute solution of hæmoglobin, all absorption bands of the emulsion are of the same intensity as the corresponding bands in the solution of hæmoglobin of similar concentration. That the depression of the band γ of hæmoglobin dispersed in oils is not due to the effect of the dispersion on the protein is shown by the fact that a similar disappearance of the band in the violet can be noted in a solution of acid porphyrin dispersed in castor oil.

All these experiments clearly show that the failure to observe the band γ of hæmoglobin when this pigment is within red blood corpuscles must be due to a purely optical phenomenon brought into play by the properties of surfaces separating hæmoglobin from the surrounding medium. At present we are unable to offer a simple optical explanation of the mechanism of this phenomenon either in the suspension of the red corpuscles or in the emulsions of oxyhæmoglobin in oils.

OBITUARIES

Prof. R. Robison, F.R.S.

THE Lister Institute has sustained a severe loss to its active strength by the sudden death on June 18 of the head of its Biochemical Department, Prof. Robert Robison. He was in his fifty-eighth year. On the previous day he was at work as usual in the Institute and was looking forward eagerly to spending a brief respite from duty at his home in Putney and tending his beautiful garden. Thus has been cut short a career of strenuous endeavour and high accomplishment in biochemistry, which is the poorer for his loss.

In 1913 Robison was appointed second research assistant to Arthur Harden in succession to W. J. Young, who had migrated to Australia and is now professor of biochemistry in the University of Melbourne. He came with the strongest credentials to his chemical training and research experience acquired at the University Colleges of Nottingham and Galway and the University of Leipzig. The War of 1914–18, during which he served in Italy and the Middle East as a captain, R.A.M.C., engaged in sanitary duties, broke the progress of his early researches at the Lister Institute; but one piece of work which Harden and he published in 1914 and which bore the title "On a New Phosphoric Ester Obtained with the Aid of Yeast Juice" was destined to presage the field of study to which, in post-war years, Robison was to devote his whole energies and which in one extension or another held his interest to the end.

It was not until 1921 that Robison was able to return to the subject of his life work, for in the immediate post-war years he had helped Harden with his investigation of the antiscorbutic properties of fruit juices and had collaborated with C. J. Martin in a valuable study of the minimum nitrogen expenditure of man and the biological value of proteins for human nutrition, a study which involved for both the strictest regimen of prescribed and uninteresting diets over considerable periods. In 1922 appeared Robison's report of the separation and purification of the hexosemonophosphoric ester, which he and Harden had found among the fermentation products of sugar by yeast juice, and it was followed in 1923 by the first of what was to prove a lengthy series of papers devoted to the carbohydrate-phosphoric esters and their physiological roles. In this first

paper he tells us how the appearance of a calcium phosphate precipitate in the hydrolysis by enzymes of the hexosemonophosphoric ester suggested to him the possibility that some enzyme might be found in the growing bones of animals which could effect the deposition of calcium phosphate and so lead to bone formation. Such an enzyme Robison found in the hypertrophic ossifying cartilage of young rats and rabbits, and so began that series of studies on the significance of the hexosephosphoric esters in ossification and in metabolism generally which, with the help of a succession of collaborators including H. D. Kay, K. M. Soames, M. Martland, Morna Macleod, E. J. King, Honor Fell, A. H. Rosenheim, M. G. Macfarlane and W. T. J. Morgan, he devoted the twenty years of life that remained to him.

In 1930 Robison was elected fellow of the Royal Society, and in 1931 he was invited to deliver the Herter Lectures in New York on the subject of his work. In January 1931 he became head of the Biochemical Department on Harden's retirement, and about the same time the University of London conferred upon him the title of professor of biochemistry. In 1933 the Royal College of Physicians honoured him by the award of the Baly Medal, a tribute he greatly valued.

Than Robison there was never a more conscientious head of a research department. Helpfulness was his keynote and an insistence at all costs on honest and accurate performance. No pains were spared, sometimes unfortunately at the cost of a constitution that was never too robust, to make the sojourn of workers in his department, whether native or foreign, both pleasant and profitable. To offices that outside bodies called upon him to perform —and they were many—he gave ever the most serious attention, and indeed his presence where chemists and biochemists foregather will be greatly missed, for he was a man of wide and cultured outlook and strongly held convictions. He leaves a widow and a married daughter, trained in her father's science, and to them we would offer our sincere sympathy.

J. C. G. LEDINGHAM.

Sir Edward Blunt, K.C.I.E., O.B.E.

SIR EDWARD BLUNT, whose death occurred on May 29, was born in 1877, educated at Marlborough and at Corpus Christi College, Oxford, and entered the Indian Civil Service in 1901. He was superintendent of Census Operations in the United Provinces of Agra and Oudh for the census of 1911. It was in that capacity, when Sir Edward Gait was census commissioner for India, that Blunt undertook the study of caste and the social structure of Hinduism, the results of which appeared in his census report published in 1912. It contains a critical examination of Hinduism as observed by him in the United Provinces, and the subject of caste, though treated there in a separate chapter, is primarily approached from its aspect as an essential element of Hinduism, which "depends a great deal more on whom one marries and what one eats and drinks, than on what one believes". The tenets of Hindu sects are also examined, and it is interesting to observe that the *Arya Samaj* is treated as a different religious unit from Hinduism proper. In 1891 the *Arya Samaj* had demanded separate classification, but the position had so far changed by 1911 that to meet various objections Blunt then classified them as *Hindu Arya*, though as an entity independent of *Hindu Brahmanic*. This arrangement had to be altered in subsequent censuses, which included the *Arya Samaj* as a mere subhead of the Hindu total.

Blunt treats caste as the result of a cross-division of guilds on a class system based on colour, on which as involving hypergamy he lays particular stress. The origin and nature of sub-castes he also dealt with, aptly illustrating the position by the Laungbarsa sub-caste of the Dhanuk caste, which in one place is strictly endogamous, in another in the same district strictly exogamous, and in yet a third exogamous as regards one other sub-caste of Dhanuk but endogamous as regards all others. Further, wherever it is exogamous it sometimes only gives girls to, sometimes only takes them from, the same sub-caste of Dhanuk. In investigating civil conditions, Blunt contributed much information on survivals of the levirate in various castes of the United Provinces, as well as comprehensive lists of the terms of relationship and a brief but very useful examination of Hindu exogamy in general.

"The Caste System of Northern India", published in 1931, covers a good deal of the same ground as the Census Report, though there is much added material such as the important chapter on "Caste and Islam". The book, however, is in one respect out of date for a book of 1931 in that it retains Risley's dogma of the civilized Aryan invader and the primitive savage Dravidian. It seems now much more probable, in view of subsequent researches, that the Dravidian-speaking population was more advanced in the apparatus of civilized life than were the Rigvedic invaders, and that the stories of contest between the enlightened invader and the black and noseless Dasyu were derived from the traditional inheritance of pre-Rigvedic inhabitants. Moreover, Stanley Rice's cogent correlation of caste with taboo suggests a much earlier origin for that system than Blunt envisages, though he specifically avoided dogmatizing. Sir Edward Blunt's researches, however, though they may not embody the latest ideas as to the origins of caste, have provided us with one of the best of the very few recent books which describe the facts of caste, and with much valuable material for its understanding; on the score of this he has earned a definite and important position among the distinguished students of that unique phenomenon.

J. H. HUTTON.

We regret to announce the following deaths:

Sir Arthur Evans, F.R.S., honorary keeper of the Ashmolean Museum in the University of Oxford, the leading British authority in the classical archæological studies, on July 11, aged ninety (see also NATURE of July 12, p. 46).

Sir William Willcox, medical adviser to the Home Office since 1919, on July 8.

NEWS AND VIEWS

Soviet Men of Science and the War

FOR the second time in twenty-five years the whole world is plunged into war; and already it has brought death to hundreds of thousands and disaster and unhappiness to millions. Prof. P. Kapitza, in a broadcast from Moscow on July 6, said that he was speaking in particular to British men of science and intellectuals and he reminded them that he had worked for some time in Cambridge under Lord Rutherford where he made numerous friends and carried away many pleasant memories. He wished to discuss the relations of the War to science and culture. The attitude of Fascism to science is that of a woodcutter who uses his axe to disable people instead of to cut wood. It is actuated by nonsensical theories leading to the desire for a dominant race. This is the opposite to the outlook of the Soviet Union, which is working for race equality and for the use of science and cultural achievement for the raising of the standard of living and the advancement of knowledge. In keeping with this the whole population shows the greatest interest in science. People in Great Britain often ask what is the attitude of the Soviet Union towards the man of science in his work. He could say that he and his colleagues are encouraged, as in England, to carry out what work they wish.

The Soviet people show great interest in British science and literature. Works by Shakespeare, Bernard Shaw and Priestley are performed, and Dickens and Stevenson, to name but a few classical British authors, are widely read; and now in the War all Soviet scientific workers are giving every support possible to the struggle of the people to preserve their country and those things which are so dear to them, as well as to liberate the enslaved peoples of Europe. With the British Empire and the United States they have a common enemy, Fascism, and he appealed to British men of science and intellectuals to collaborate with their Soviet colleagues with whom they have so many ideals in common.

New Building for the Soviet Academy of Sciences

BEFORE the outbreak of hostilities, the main building of the new home of the Academy of Sciences of the U.S.S.R. had been started on the Krimsky Embankment of the Moscow River. The building was designed by the Soviet architect, Prof. A. V. Shchusev, who recently stated that this would be one of the largest buildings in the Soviet capital—755 ft. long, 328 ft. wide and $131\frac{1}{4}$ ft. high. The new building will house the presidium of the Academy, twelve institutes, a library with a depository for four million books, and two exhibition halls. One of the features of the building is a round conference hall, 118 ft. in diameter, with comfortable seating accommodation for a thousand persons. Connected with each of the two exhibition halls will be a semi-circular auditorium seating a hundred and fifty persons and specially fitted for demonstration lectures.

Each of the twelve institutes to be housed in the new building will have a meeting hall, a hall with cinema apparatus, laboratories and reception rooms. If circumstances permit, the major part of the construction work will be completed by 1943, when the presidium and the institutes of the Academy will begin moving into their new quarters. Alongside the main building will be erected a large depository for fifteen million volumes, and two museums—the History of the Earth and the History of Animal Life.

Large Aircraft for the R.A.F.

IT has recently been revealed that twenty Boeing "Flying Fortresses" (B-17.C.type), all of which have been flown across the Atlantic, are now in service with the Royal Air Force. The official R.A.F. title for these will be "Fortress 1". Further supplies of an improved design (B-17.E.) are under construction in the United States. These bombers, the largest at present in service, have a span of 104 ft. and a length of 68 ft. They are equipped with four engines of 1,200 h.p. each, supercharged, can maintain a speed of 305 miles an hour at an altitude of 25,000 ft., and have a ceiling of 36,000 ft. With speeds and heights of this order they can put up a reasonable defence against enemy fighters, and the problem of providing them with fighter escorts is simplified as their performance is comparable to that of their protectors. Particular attention has been paid to protective armament, the wide angle of fire over which the machine guns can traverse giving almost complete cover in any direction.

The load carried by these machines is 5,000 lb. over a range of 2,000 miles. This enables very large individual bombs to be carried, that are considered to be necessary for the destruction of certain types of targets not always susceptible to the effect of a similar total weight of smaller bombs, carried in a number of machines of less capacity. Also there is the tactical advantage of the relatively smaller requirement in trained personnel needed for the one large machine. The Minister of Aircraft Production, Lieut.-Colonel Moore-Brabazon, recently announced in Parliament that although these machines were the biggest in the world at the time they were made, we have now under construction "three types bigger than anything in America".

The Iraq Meteorological Service

THE fourth annual report of the Director of the Meteorological Service of the Government of Iraq, for the year ending March 31, 1940, deals with a period during which a variety of causes operated to increase the difficulties in the way of the orderly

development of this infant service (Government of Iraq: Ministry of Defence: Meteorological Service. Annual Report of the Director, No. 4: Year ending 31st March 1940. Pp. 30. Baghdad: Government Press, 1940). Measures taken in previous years to provide the most efficient service of information about the existing and anticipated weather on the various air routes of civil aviation "blossomed and bore fruit towards the end of the year", to quote the report, an achievement which practically coincided in time with a reduced demand for such information resulting from reduced civil aviation on account of the War. In addition there were the minor disturbances of continuity arising from the transfer of the service from the administrative control of the Officer Commanding the Royal Iraq Air Force to the Director of Civil Aviation and from a change of directorship, although the latter did not occur until the fourth day of the last month of the period covered by the report, when Mr. J. S. Farquharson relieved Mr. J. Durward, the first full-time director.

But the greatest obstacle to progress in national meteorological organization remained, as in previous years, that of getting suitably educated staff of the right calibre willing to take up the openings that become available in the expansion of such a youthful service. A consequence of this was that several of the observatories were maintained single-handed without a day's respite—no mean achievement when the climate of Iraq is taken into consideration. The calling up for military service of some of the trained staff was a contributory cause of this state of affairs. As regards the work of the Service, the report shows that a large part of this consisted in the carrying out, in spite of the obstacles just referred to, of a fixed scheme of distribution of information for the benefit of aviation, and supplying answers to various climatological inquiries. In addition, the first three of a series of non-routine publications described as "Occasional Publications" were completed. Of these the first and third dealt with climatological statistics —principally monthly mean temperature and rainfall—while the second was concerned with administrative regulations.

Expansion of Electrical Industries in Canada

MR. JOHN R. READ, president of the Canadian Westinghouse Co., Ltd., gave an interesting broadcast in Canada on the vital part being played by the Canadian electrical industries in the war effort (Bull. Hydro-Electric Power Commission of Ontario). He stated that the Canadian worker has more electrical energy to call upon than anyone else in the world except the Norwegian. More than 80 per cent of the power used for all purposes in Canada is electric power, and to-day the electrical plants of the Dominion can produce some nine million h.p., more than five times the amount of electric power which was available for the service of Canadian industry during the War of 1914–18.

Enormous supplies of power and power equipment are required in the manufacture of explosives. Because Canada has the power available, a total of 106 million dollars is being expended in creating great chemical and munitions plants in various parts of the country. A large new aluminium plant is now being constructed in Canada, representing an investment of about fifty million dollars, and capable of producing when completed enough aluminium a year for the construction of about fifty thousand military aeroplanes. This will be an installation of 700,000 h.p.

It is much the same story with respect to all those other metals vital in war—gold, copper, nickel, lead and zinc. Almost one tenth of all the electric power used in Canada is employed by the mining industry. Ample power supplies have made it possible for the mines to increase their production to meet war needs. One of the very striking differences between the present War and that of 1914–18 relates to communications. Since 1918, the whole new world of radio has emerged, and radio equipment makes possible the constant co-ordination of military action. Radio is also a vital link in the national life. Already scientific men of the industry have moved far in the fields of television, facsimile transmission, electron optics and extremely high frequencies. More than 60,000 Canadians are engaged in the electrical industry. Their wages and salaries amount to more than one hundred and ten million dollars a year. The electrical industry of Canada well realizes the task which war imposes, the duty which it owes to democracy, to Canada, and to the ideals of its founders.

The Gas Industry in War-time

THE seventy-eighth general meeting of the Institution of Gas Engineers was held in London on June 11 under the presidency of Mr. George Dixon of Nottingham. At the luncheon Mr. Oliver Lyttelton, then president of the Board of Trade, and Sir Peter Bennett, of the Ministry of Aircraft Production, spoke in complimentary terms of the resilience of the industry and its valuable services under present war conditions. The technical business consisted in the discussion of a symposium in "The Gas Industry, 1941 and After"—nine short papers on topics of current interest and importance. These revealed a strong movement for reorganization and administrative concentration of the industry which it is felt consists of an excessive number of producing and distributing units. The number of standards of calorific value is excessive, with consequent undue multiplication in patterns of appliance and their cost. The success of grouping small undertakings and the establishment of 'gas grids' in promoting the freer use of public gas supply was taken as an example to follow. There are obstacles to reorganization in an old industry consisting of numerous and sometimes small local units. If, however, desirable changes are not undertaken spontaneously, it was suggested that they might be enforced by national action to meet urgent and national needs. Coal carbonization industries with their production of liquid fuel may, under post-war economic conditions, acquire a new and greater importance.

Road and Rail Transport in India

AN article by C. N. R. Rau in *Current Science* of March on "The Co-ordination of Road and Rail Transport" reviews recent experience of transport in the Empire both before and during the War, with special reference to India, and endeavours to indicate basic principles of service which should determine both the choice and organization of transport. Discussing the handicaps under which rail transport generally labours, Mr. Rau considers that the plea for a 'square deal' for the railways is well founded. He suggests that investigation is still required to determine how far co-ordination of inland transport can meet the recognized ideals of service, whether in the transport of goods or passengers, or from the point of view of operating efficiency and safety, and indicates that both road and railway transport services might explore the field of public relations much more thoroughly. Emphasizing the importance of co-ordination, once it is clear as to the types of traffic best suited for one form or other of transport, he suggests that legislative or Government control, without nationalization, could with a judicious road policy, so shape the transport system of India that the two methods would work as complementary units, each performing the work best suited to itself and rendering the best service to the community.

The value of agreements between the two systems, of mutual recognition, and the organization of road transport with reference to railway stations, for example, by the use of railway stations as bus termini, the interavailability of tickets, publicity of one service on the other, the application of "undue preference" and "common carrier" clauses to both systems, are among concrete suggestions advanced for the promotion of efficient transport in India, as well as consideration of the establishment of an organization under joint auspices, entrusted with the task of collecting, analysing and collating all relevant information in regard to problems of common interest. Road operating statistics should be published on the same lines as railway statistics, and the State should insist on the organization of road haulage on the lines adopted by the railways, so that the two systems can negotiate on an equal footing and share the benefits of any co-ordination schemes.

Diesel-Electric Tube Locomotive

THE London Passenger Transport Board is utilizing parts of old railway coaches from the "Central Line" of the underground system for building at its Acton works Diesel locomotives for hauling ballast and maintenance trains, or for emergency use in the 'tubes'. These duties are at present performed by tank-type steam locomotives. It is arranged to collect current from the live 600-volt track rail, or be propelled by its self-contained generating set as circumstances may require, and it is capable of hauling a 600-ton train on the level or one of 300 tons up a 1 in 34 gradient. The length of the vehicle is 57 ft., its width 8 ft. 2 in., its height 9 ft. 5 in., and the tare weight in running order is 62 tons 12 cwt. According to the *Electrical Review* of May 16, only the oil engine and generator with some switchgear had to be purchased in fabricating the train. The passenger compartments of two old driving cars were cut off, leaving the equipment compartments with motors and driver's cabs; these were joined together. The locomotive can be controlled from either end. Its engine is of the Petter 'superscavenge' airless injection, two-stroke cycle, cold starting type. The six cylinders develop 506 b.h.p. at 675 r.p.m. The engine is started by means of compressed air at 350 lb. per sq. in. The generator, which was made by the Brush Electrical Engineering Co. Ltd., is a level-compounded shunt machine with a continuous rating of 750 amp. at 450 v. The traction equipment consists of two series-parallel sets with automatic relay controlling notching.

Control of Pig Raising

C. P. McMEEKAN has furnished what, in view of the present food situation, should prove a valuable analysis of the growth and development of the pig with special reference to carcass quality characters. The five parts (*J. Agri. Sci.*, **30**, 1940; **31**, 1941) with their appendixes have been conveniently issued together. The aim of the work is to provide a base from which to control the raising of pigs as meat-producing animals. It is, therefore, particularly concerned with the effects of nutrition upon not only the growth and size of the pig as a whole but also upon the quality of the meat produced. The author admits that the term 'meat quality' is not possible of exact definition in a form capable of universal application, but some approximation can be made thereto. Of course it will vary with the use to which the meat is to be put and also with the local tastes and requirements. The bulk of the memoir is naturally concerned with the statement of a number of experiments and an analysis of their results, but general ideas are not overlooked and the work concludes with a review of the main principles that emerge and their wider application even to human beings.

British Natural History

DESPITE the increasing difficulties and demands upon the spare-time, amateur as well as professional, natural history continues in Great Britain. The summer *Bulletin of the British Empire Naturalists' Association* records the continuance of branch activities at Bournemouth, Merseyside, Derbyshire, North Cotswold, London, Manchester and Lancaster; in fact only two branches have closed since the outbreak of war. 1941 field records include the first definite nesting of the fulmar on St. Bee's Cliff, Cumberland; Bewick's swans and a green sandpiper on spring passage in Lancashire; a fire-crest at Stanmore, Middlesex, on April 6; siskins at Farnham, Surrey, April 30, and a bird migration survey over twelve counties. The 1940 edition of the Burton-on-Trent Natural History and Archæological Society records has appeared and directs attention to the opportunity for studying the changes the war-time felling of woods will have upon bird, plant and insect life.

The Merseyside Naturalists' Association is shortly publishing its new book on the birds of west Lancashire and west Cheshire; the Blackburn Naturalists' Field Club reported a record attendance, averaging two hundred, at its indoor evening meetings last winter, and the recent summer meeting of the North-East Lancashire Naturalists' Union at Darwen was very well attended. The Thunder Census Organization is carrying on its work and has just issued its fifth annual report from Langley Terrace, Oakes, Huddersfield, and particulars of trees struck by lightning are being collected. The Liverpool Botanical Society is continuing its field work for the publication of its "Flora of South Lancashire" and the North of England Zoological Society, Chester, has made its monthly journal the organ for reporting the activities of other zoological collections since the *Animal and Zoo Magazine* of the London Society suspended publication, and London, Dudley and Maidstone Zoos contribute to the June issue.

Medicine in Saint-Simon's "Mémoires"

IN a recent paper on this subject (*Proc. Roy. Soc. Med.*, **34**, Sect. Hist. Med. 31; 1941) Dr. J. D. Rolleston claims that this work, which covered twenty-one years of the reign of Louis XIV and eight years of the Regency, contained many passages of medical interest, though they had received little attention from medical historians. They could be classified under the headings of prevalent diseases, portraits of contemporary doctors and miscellaneous topics. Small-pox was by far the most frequent of all the diseases mentioned by Saint-Simon, and its prevalence among royal personages and courtiers was a striking proof of the efficacy of Jenner's discovery, as since that time the disease was almost unknown among the upper classes in whom conscientious objectors were rare. Among chronic infections described in the "Mémoires" syphilis undoubtedly held the first place and claimed several courtiers of both sexes among its victims. Many cases of lung disease, probably of a tuberculous nature, are also mentioned. As might be expected owing to their indulgence in highly nitrogenous diet, large consumption of alcohol and lack of exercise, a great number of courtiers as well as Louis XIV suffered from gout. Several examples of nervous and mental diseases as well as alcoholism and cancer are also alluded to by Saint-Simon. Of the thirteen surgical operations mentioned five were for stone in the bladder and four for fistula *in ano*, a complaint which, after the operation on Louis XIV, became as fashionable as appendicitis did more than two centuries later after the operation on Edward VII.

The "Mémoires" also contain brief indications of three diseases—achondroplasia, spondylitis deformans and hæmophilia—long before they were described in scientific medicine. As regards his attitude towards the medical profession, Saint-Simon, like many other distinguished laymen before and since his time, did not appear to have a liking for doctors, as is shown by the frequency with which he declared that they had not understood the nature of the disease which they were treating. On the other hand, he was unsparing in his eulogies of individual doctors, such as Fagon, Louis XIV's physician, Mareschal, his surgeon, and Hyghens, the king of Spain's physician who attended Saint-Simon during his attack of small-pox. The miscellaneous topics of medical interest mentioned in the "Mémoires" include longevity, sexology, spas, poisoning, post mortem examinations and the illnesses of Louis XIV.

History of Endocrinology

IN a recent paper on this subject read before the Section of the History of Medicine of the Royal Society of Medicine (*Proc. Roy. Soc. Med.*, **34**, 303; 1941) Dr. A. P. Cawadias said that three periods could be distinguished in the historical development of endocrinology. The first was the descriptive period, the second was one of analytic endocrinology and the third or contemporary period was that of synthetic endocrinology. The first description of endocrine diseases was given long before there was any accurate knowledge of endocrine physiology, being found in the writings of Hippocrates, who studied hypo-orchidism and climacteric hypo-ovarism. Only after some advance was made in the knowledge of glandular physiology, however, were endocrine diseases introduced into nosography. The earliest of these was hypothyroidism, studied by T. Curling in 1850 and later by C. H. Fagge in 1871 and Sir William Gull in 1873. Hypo-adrenalism was described by Addison in 1855, when endocrine nosography first made a real start. A notable advance in the history of endocrine diseases was made by the introduction of endocrinotherapy. This began with Brown-Séquard in 1889, reached a notable peak with the introduction of thyroid organotherapy by G. R. Murray in 1890, and developed intensively in recent years, outstanding events being the introduction of insulinotherapy by Banting in 1921, of the various sex hormones and of cortin.

The Wyperfeld (Mallee) National Park

THE Mallee National Park in Victoria, known as "Wyperfeld", an account of which appeared in NATURE of August 12, 1939, p. 272, has received a substantial addition of 51,840 acres, owing to the far-sighted action of the acting premier of Victoria, Mr. Lind. This makes a total area of 138,700 acres. The land added, known locally as the "Desert", is useless for purposes of production, but contains the mound builder, known as the 'lowan', and is a feeding-ground for birds. The Park is situated in the most arid part of the State with a capricious rainfall of 9 in. and great evaporation. In spite of this dryness it is well stocked with birds of the cockatoo and parrot family, also lowans and emus. It also contains a number of black-faced kangaroo. There is at present only one well in the area, and exactly where these animals get the necessary water is not known. The trough at the well is used by some of the birds and by bees, but so far the kangaroos have not been seen to use it. A somewhat similar problem of water supply can be seen in the Egyptian Desert bordering on the Mediterranean which, whereas it is lifeless in the day-time, is stocked with jerboas and various reptiles at night.

A Matrix Machine

With the growing application of matrix algebra, especially in the factorial analysis of psychological data, there is an increasing demand for a machine that will multiply matrices. Such a machine has now been produced in the United States by the International Business Machines Corporation, assisted by a research grant from the Carnegie Foundation, and is described in *Psychometrika* (5, 289; 1940). It uses an electric circuit in which one set of connexions is made by special marks on record sheets, one for each row in the first matrix, and the other set by plug wires corresponding to a column of the second matrix. The product of a matrix with any number of rows and up to 15 columns by a second matrix consisting of a single column is thus found, the results being read off on a meter. If the second matrix has more than one column, one column at a time is dealt with. The machine is in use in the psychological laboratory of Dr. L. L. Thurstone of Chicago, and the results appear to be accurate to two significant figures.

The International Seismological Summary

The International Seismological Summary for the second quarter of 1934 has just been received. It contains the determinations of 144 epicentres by the workers at Oxford, from all the available evidence sent by seismological observatories throughout the world. Sixty-two of these epicentres are new and eighty-two are repetitions from old epicentres, again showing the tendency of earthquakes to recur. Fifteen of the earthquakes have deeper focus than normal and one on June 29, 1934, at 8h. 25m. 20s. G.M.T., has a calculated focus 0·106 of the earth's radius below normal, which is at a greater depth than that of any earthquake previously treated in the summary. The epicentre of this shock was at 6·1°S., 123·4°E., which is in the Banda Sea close to and immediately east of the town of Baoebaoe in the island of Celebes in the Dutch East Indies. The area is well known to be frequented by deep focus earthquakes. In view of the accuracy with which the epicentre is known, the numerous data have been used to extend a table of corrections which may be applied to epicentral distances to produce agreement between observed and calculated times of the *P* wave.

Society of Chemical Industry

At the sixtieth annual meeting of the Society of Chemical Industry, held on July 8, Dr. W. Cullen, the well-known consultant in chemical and metallurgical engineering, was elected president in succession to Prof. J. C. Philip, who has occupied the post for two years. According to the Council's report, membership at the end of 1940 stood at 3,920, a decrease of only 77 on the total for the previous year; since then, however, many hundreds of new members have joined the Society, a reflection no doubt of the expanding chemical industry of Great Britain. The Society's Medal, the oldest of its distinction, has been awarded to Sir Robert Pickard, director of research for the British Cotton Industry Research Association at the Shirley Institute, who delivered an address on "The Influence of Science on National Life". The Society is to be congratulated on successfully overcoming the difficulties created by two enforced evacuations by its offices.

Announcements

Prof. F. A. Lindemann, who had been created a baron (see Nature, June 21, p. 772), has taken the title of Baron Cherwell, of Oxford in the County of Oxford.

Lord Horder has been appointed by the Minister of Food to be his personal adviser on medical aspects of food problems.

The first Charles Chree Medal and Prize of the Physical Society will be presented to Prof. S. Chapman, professor of mathematics in the Imperial College of Science and Technology, on July 25. Prof. Chapman will deliver an address on (1) Chree and his work on geomagnetism; (2) geomagnetic time relationships; (3) the future of world magnetic surveying.

Prof. J. B. Conant, president of Harvard University, was elected an honorary fellow of the Royal Society of Edinburgh at a meeting held on July 7. At the same meeting the Gunning Victoria Jubilee Prize for the period 1936–40 was presented to Sir James Irvine for his distinguished contributions to organic chemistry; and the Makdougall-Brisbane Prize for the period 1938–40 to Mrs. E. L. Ince, on behalf of her husband, the late Dr. Edward Lindsay Ince, for his papers on "The Periodic Lamé Functions", published in the *Proceedings* of the Society.

The Edinburgh Association for Sending Medical Aid to Foreign Countries this year celebrates the centenary of its foundation.

The following appointments and promotions in the Colonial Service have recently been made: B. de L. Innis (agricultural superintendent, Gold Coast), assistant botanist, British West Indies, Central Sugar Cane Breeding Station, Barbados; J. T. Purvis (senior assistant livestock officer), agricultural officer, Tanganyika Territory.

To promote the interests of science in the south of the United States, a new Southern Association for the Advancement of Science has been organized. Dr. George D. Palmer of the University of Alabama, who served as president during the organizing period, is now secretary-treasurer. Dr. G. H. Boyd of the University of Georgia is president-elect. In addition to the encouragement of scientific research in general and its application to problems of the South in particular, the declared objectives of the new Association include the setting up of a roster of Southern research talent available not only for specific southern problems but also for possible contributions to national defence.

Tastes of Oxygen and Nitrogen at High Pressures

WHILST carrying out experiments on behalf of Admiral Sir M. E. Dunbar-Nasmith's Physiological Sub-Committee for saving life from sunken submarines, we and other subjects have had occasion to breathe oxygen, air and other gas mixtures at high pressures.

When oxygen was breathed at 6 atmospheres, several subjects noticed a peculiar taste, which was enhanced at 7 atmospheres. None of them noticed it at 3 atmospheres. The taste is both acid and sweet. Two subjects described it as "like dilute ginger beer", and "like dilute ink with a little sugar". It was felt unevenly, by one subject mainly on the back of the tongue, by another beneath it. In one case it persisted for some minutes after ceasing to breathe oxygen. It may be remarked that although oxygen is a convulsant at such high pressures, it can be breathed with complete safety for long enough to taste it.

In air at 10 atmospheres, and sometimes even at 8 atmospheres, a number of subjects reported a taste which is variously described as harsh, metallic, and indefinable. It is certainly not due to oxygen, and one subject who tasted it regularly in air did not do so when mixtures in which the nitrogen of air had been replaced by helium or hydrogen were breathed at 10 atmospheres. We therefore attribute it to nitrogen.

Not all subjects reported these tastes. This was probably often due to the fact that other sensations were distracting them, and to the narcotic effect of nitrogen at high pressures. However, one subject who was repeatedly on the look-out for both tastes has never tasted nitrogen, and only tasted oxygen very faintly at 7 atmospheres. His sense of taste is, however, poor as a result of cerebral concussion.

We conclude that the taste threshold for oxygen lies below 6 atmospheres and for nitrogen below 8, in about half of the persons tested. So far only one person has reported an abnormal smell, in compressed air, but perhaps oxygen and nitrogen may have smells at still higher pressures.

It is clearly inaccurate to describe a gas as inodorous and tasteless. On the contrary, most or all gases may be expected to display these properties at sufficiently high pressures, just as they liquefy at sufficiently low temperatures. Whether men can survive the pressure under which, say, hydrogen develops a taste or smell is, of course, as yet unknown.

We have to thank the Admiralty and Messrs. Siebe Gorman and Co. for making this research possible.

Ascorbic Acid and Resistance to Low Oxygen Tension

IN an article published in the *Lancet* of June 28, Stewart, Learmonth and Pollock record experiments which show that the intravenous administration of ascorbic acid prolongs the life of cats after severe hæmorrhage. They suggest that ascorbic acid secures a more adequate supply of oxygen to the tissues.

Experiments which have been carried out in this Institute by Dr. B. G. B. Lucas, in an attempt to make oxygen more available to the tissues of animals subjected to low atmospheric pressures, have yielded similar results. Both methylene blue and ascorbic acid, administered intraperitoneally, have been found to increase the resistance of mice and rats to low oxygen tensions. A mouse, injected with methylene blue or ascorbic acid, may survive a number of consecutive exposures to atmospheric air at a pressure of 120 mm. mercury, while, on each occasion, an untreated companion succumbs.

Pharmacological Classification of Steroid Hormones*

UP to the present, the physiological classification and terminology of steroid hormones was based either on one of their outstanding actions ('œstrogens', 'progestins') or on their source of origin ('corpus luteum hormone', 'adrenal cortical hormone', 'testis hormone'). Such a classification is no longer possible, since we know, for example, that 'testis hormones' may originate in the adrenal cortex and may exert 'œstrogenic' actions. In spite of the considerable overlapping between the physiological actions of the steroid hormones, they can and must be classified into certain groups. It is felt that the best solution of the problem is to *classify the steroid hormone actions according to the degree to which they are able to imitate or substitute for the function of a certain endocrine gland.* Accordingly these groups might be given names reminiscent of the glands and yet indicating that this does not imply that such glands are the only source of the hormone.

Thus progesterone imitates the action of a corpus luteum and œstradiol that of an active follicle even though these hormones may originate from cells other than those of the corpus luteum and the ovarian follicle respectively. The grouping of the steroids into œstrane, androstane and pregnane derivatives is a satisfactory basis for the classification of their

* Abridged.

chemical properties. As a designation for the whole groups of hormones having a structure reminiscent of the sterols, Callow and Young[1] suggested the name of 'steroid' which has generally been accepted. The Greek ending 'oid' derived from ειδος meaning form, has often been used in pharmacology to designate compounds similar in their actions to those described by the work preceding this ending (for example, toxoid). Accordingly, the four main types of steroid hormone-like actions might be described as corticoid, luteoid, folliculoid and testoid. Thus without introducing any essentially novel terms, we could classify the steroid hormones into four main pharmacological groups according to the principles mentioned above :

Corticoid = having activity of : cortin, adrenal cortical hormone, principle maintaining life of adrenalectomized animals, etc.

Luteoid = having activity of : progestin, corpus luteum hormone, progesterone, luteine, β-hormone, kythine, luteohormone, corporin, relaxin, mucifying hormone, luteocrinine, etc.

Folliculoid = having activity of : œstrin, œstrogenic hormone, feminine, gynæcogenic hormone, menformon, folliculin, α-hormone, follicular hormone, female hormone, etc.

Testoid = having activity of : androkinin, male hormone, testis hormone, androgenic hormone, etc.

It may incidentally be mentioned that the term 'cortin' has now lost its original meaning as a generic term for adrenal cortical hormone activity since Hartman *et al.*[2] now distinguish between the "vital factor, cortin" and the "sodium factor". This means that desoxycorticosterone acetate is both a 'cortin' and a 'sodium factor', while some of Hartman's cortin preparations are apparently devoid of the latter activity. If this type of subdivision were carried over to the group of the testoids, androsterone would have to be called prevailingly a 'prostate factor' and testosterone a 'seminal vesicle factor'. Subdivision carried to this degree is of no particular value as it eventually leads to the mere statement of single characteristics which can much better be done by the generally accepted practice of merely stating the degree to which the compound has 'metrotropic', 'mammotropic', 'renotropic', pituitary-enlarging, life-maintaining, etc., ability. While the determination of all these activities is evidently of importance, it is felt that for the reasons mentioned above, the single action can be used as a basis for a classification. On the other hand, the classification suggested in this note has none of these deficiencies, and the proposed group names are equally applicable to artificial compounds and true hormones. It is hoped they will prove useful at this time when so much work is done on a multitude of newly synthetized steroid compounds with hormone activity.

Nomenclature of Pituitary Autacoids

THE nomenclature of pituitary autacoids is unsatisfactory, and current terminology with reference to those of the anterior lobe is particularly at fault. The terms thyrotropic and gonadotropic are in general use. These terms are misleading. The Greek word τροπος or τροπη means *a turn, return,* or *turning about* and the verb τρεπω from the same root can be used transitively to signify *direct* or *guide*.

We have long-established precedent for this root in current biological literature. The *phototropic* or *geotropic* behaviour of a plant signifies that it turns towards or away from light or the centre of the earth. The same words have also been used to describe the behaviour of an animal when it moves to or from a source of light or the earth's centre. Students of animal behaviour have very properly recognized that this is inconsistent with scientific usage. Consequently they have substituted *phototaxis* and *geotaxis*.

Dr. A. S. Parkes has suggested the use of the term *gonadotrophic* instead of *gonadotropic*[1]. The meaning of the Greek root of the suffix *trophic* would indicate that the hormone feeds the gonads. This is far from certain and it is possible to choose a more appropriate root which can be applied to all the activities of the pituitary gland. It is certain that there is some physiological connexion or link between the specific activities of the anterior lobe and the thyroid, gonads, etc.

One Greek word which meets our requirements is δεσμος, which means a bond, fetter, or link. This suggests the following terminology for the anterior lobe autacoids :

(1) thyrodesmic (*thyrotropic*)
(2) blastodesmic or *growth-promoting*
(3) oodesmic or *follicle-stimulating*
(4) xanthodesmic (*luteinizing*) } gonado-desmic
(5) androdesmic or *testicle-stimulating*
(6) galactodesmic (*galactogogue*)

One objection to the items of this list is that growth-promoting is sufficiently explicit. For those who prefer native words to international terms, thyroid-stimulating is certainly better than thyrotropic.

Existing terminology of the posterior lobe autacoids is not open to the same objections. The term oxytocic is not inherently inconsistent with established usage of Greek affixes. Still, it is open to the criticism that it contains no familiar root which suggests its meaning. For the English-speaking scientific worker, uterine stimulant is therefore a better term than oxytocic activity. From every point of view Hogben's *melanophore stimulant* is preferable to *chromatropic*. Until it is possible to distinguish between the substances responsible for melanophore stimulation and erythrophore stimulation the adjectives *melanodesmic* and *erythrodesmic* might be appropriately used. *Pressor substance* is sufficiently explicit from the point of view of the English-speaking world and is in accordance with international usage. So also is the term *anti-diuretic*. For those who prefer a uniform nomenclature, I suggest the following :

(1) hæmodesmic (*pressor*)
(2) splanchnodesmic (*oxytocic*)
(3) (*a*) melanodesmic (*b*) erythrodesmic
(4) nephrodesmic
(5) leucodesmic (the at present hypothetical "*W*" substance of Hogben and Slome).

A Possible New Cure for Acarine Disease of Honeybees

ACARINE disease, sometimes still known as 'Isle of Wight disease', as its name implies is caused by the invasion by the mite *Acarapis woodi* of the thoracic tracheæ of the adult honeybee. Although no longer epidemic, this complaint still causes the complete destruction of many colonies of bees annually and the serious weakening of many others.

To kill the mites inside the tracheæ of an infected bee, some volatile substance which exerts a marked differential toxicity upon the bee and *A. woodi* would appear necessary. Up to the present a small number of substances or mixtures has been found to have properties tending towards the desired objective. These have not, however, been found to be entirely satisfactory. Work has therefore been carried out here during the last two and a half years in an attempt to find a volatile material which kills *A. woodi* in the tracheæ of the honeybee, does not harm the adult bees or their brood, and is simple and cheap to apply. Many substances were tested with varying degrees of success and it has been found that the vapour of terpineol, a heavy faction of crude pine oil, gives the results desired, being highly toxic to *A. woodi* but harmless to bees. In one experiment twenty-five bees which were heavily infected were subjected to the vapour of terpineol for five days and, at the end of this period, all the mites were found to be dead, whereas twenty control bees were all found to contain many live mites.

Experiments are now being conducted to determine a simple and satisfactory method of administering terpineol to a colony of bees.

It is hoped that the results obtained with this substance will be published in full in the near future.

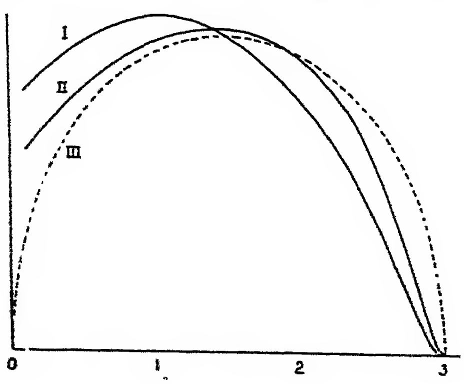
Production of Electron Pairs

SOME time ago we described a method[1] for calculating rigorously (neglecting screening) the cross-section for production of electron-positron pairs in the field of a nucleus by a beam of γ-rays. This method also gave the energy distribution of the electrons or positrons. Results were given for lead, atomic number $Z = 82$, for γ-rays of energies $h\nu = 5\ mc^2$ and $3\ mc^2$, and were in reasonably good agreement with experiments on pairs produced in



thin foils. Calculations have now been made for $Z = 54$, $h\nu = 5\ mc^2$, to enable direct comparison to be made with Wilson chamber experiments on xenon and iodine. The final results contain about 20 per cent of (additive) extrapolated terms and should be accurate to about 10 per cent. The old calculation for lead has been extended and a small error corrected: the revised figures are given below.

The values of σ, the cross-section per atom for absorption by pair production by γ-rays of energy $5\ mc^2$, for atomic numbers 82 and 54 are given in the table, together with the values calculated on the Born approximation[2]. The values of $\bar{E}_+ - \bar{E}_-$ are also given, where $\bar{E}_+$ and $\bar{E}_-$ are the average energies of the positron and electron respectively.

Z	54	82
$\sigma \times 10^{24}$	1·1	3·0
$\sigma \times 10^{24}$ (Born)	1·1	2·5
$(\bar{E}_+ - \bar{E}_-)/mc^2$	0·27	0·51

The energy distribution of the pairs produced by radiation of energy $5\ mc^2$ is shown in the accompanying figure. The abscissæ are electron-energies in units of mc^2 and the scale of the ordinates is arbitrary, the curves being adjusted to have the same area. Curves I, II and III are respectively for $Z = 82$, $Z = 54$ and the Born approximation. Curves I and II theoretically tend to a finite limit for zero energy of the electron, but these values have not been calculated.

Thin Glass for Microscope Cover-Slips

MICROSCOPISTS will note with interest and appreciation the recently recorded centenary of the production by Messrs. Chance Brothers of thin glass for microscopic purposes[1].

There is good reason to believe that the production of this glass was due to the insistent and increasing demand by the early members of the Royal Microscopical Society. It is recorded that one of the first things the Council did in 1840 when thin flatted sheets first became available was to consider and standardize the size of the specimen slide at 3 in. × 1 in.—which size has since become universally adopted—and to install a device for the use of members for cutting both slides and cover-glasses from these sheets.

While it would be difficult to produce with certainty the earliest instance of the use of glass in place of talc, there is strong evidence to show that it was used for some ten years before thin flatted sheets became available through the enterprise of Messrs. Chance Brothers.

In 1831 Andrew Ross made the first achromatic objectives on Lister's formula. In 1832 J. T. Cooper suggested the use of Canada balsam as a mounting medium for the preservation of microscopic specimens. Now in both these matters the use of the talc disk would appear to be impracticable; and further, the development and purpose of the correction collar to high-power objectives which Ross brought out in 1837 was to correct the spherical and chromatic

aberrations introduced by the adoption of the cover-glass.

It appears to have been customary in those early days for microscopists to select small fragments of thin glass obtained from large bubbles blown to bursting, and to use the suitable pieces thus obtained for cover-glasses. The helpful warning then given to the members not to use too much pressure in placing the cover-glass over the specimen had an obvious meaning. A few of these early slides are still preserved in the Society's historical collection.

The production in 1840 by Messrs. Chance Brothers of what was then described as thin and very thin flatted sheets was a valued contribution to the study and advancement of scientific microscopy in which Great Britain then led, and continues still to lead, the world. Microscopists everywhere still regard with warm congratulation the long and honourable record of pioneering achievement of this distinguished firm in the production of glass for optical and other scientific purposes.

"A School Chemistry"

As the author of "An Introduction to Chemistry", I wish to protest against the review of this book which appeared in NATURE of March 22. The reviewer has devoted so much space to criticisms of controversial or trivial matters that he has failed to emphasize the special features of the book. The general character of several of his remarks can be judged from the following selection, to which I have added some comments.

(1) " . . . phosphorus was discovered by Brand, not Brandt, probably in 1674 not 1669." The implication in the first part of the statement is incorrect; Brand, not Brandt, is given in the text. The reviewer may be correct about the date, but a letter from Brand to Leibniz (G. H. Peters, *Arch. Geschichte Naturw.*, **4**, 206 (1912); **7**, 92 (1916)) indicates the date 1669, and this appears to have been accepted by Mellor, "Thorpe's Dictionary" and the "Encyclopædia Britannica".

(2) "The statement that argon was first called 'aeron' (p. 118) is new to the reviewer, but may be correct." The suggestion in this statement is ungenerous. The author's remark about aeron is substantiated by a letter Rayleigh wrote to Lady Frances Balfour in 1894 (actual quotation, pp. 212–13, "Crucibles", by B. Jaffe).

(3) "The style is generally good, but it is surprising to find on p. 482 the direction to 'tip' a solid into a vessel." The use of the word 'tip' is in accordance with the definition given in the Oxford Dictionary, and the author has been informed by two well-known examiners that they see no reason for criticism on technical grounds.

(4) "Black's date is 1755 not 1775." The correct date of 1755 is given higher up on the same page, indicating that a slip was made in proof-reading. The reviewer might, instead, have pointed out that this section gives a fairly detailed account of Black's masterly researches on the mild and caustic alkalis, and that this is unusual in a School Certificate text-book.

(5) "the definition of a 'pure substance', as given, would include solutions." The author was careful to amplify his definition of a compound (not substance) by stating that it included the law of constant proportions, namely: "a pure compound always contains the same elements in the same proportions by weight." This effectively excludes saturated solutions and eutectics, since their composition varies with temperature and/or pressure.

(6) "Jabir and Geber are confused, as in other places (pp. 257, 310, 344, etc.)." Dr. E. J. Holmyard, an authority on Arabian science, says in "The Great Chemists", p. 11, "The greatest chemist of Islam . . . was Jabir ibn Hayyan, who is more familiar to Western readers under the name of Geber". The "Encyclopædia Britannica" confirms this view, so that there is at least some authority for the author's 'confusion'.

A. C. CAVELL.

Uppingham.

One object of a review is to direct attention to points in a book on which there may be differences of opinion even among experts, and it is generally accepted that such discussion is useful and interesting. Mr. Cavell has raised one or two points which merit further consideration.

(1) In an elementary work, where no authorities are quoted, it is best to follow the modern experts. The date 1674 is now generally accepted for the discovery of phosphorus, as Mr. Cavell now seems to imply, and it is given, for example, in Roscoe and Schorlemmer and in the new edition of Mellor's "Modern Inorganic Chemistry". The matter of the letter of Leibniz is dealt with in special publications. The references to Mellor (presumably the large "Treatise", in which all statements, right and wrong, are quoted), Thorpe's "Dictionary" and the "Encyclopædia" are beside the point. The author of a book is expected to use critical judgment.

(2) As the reviewer stated, the point about the name of argon was new to him but might have escaped his attention. He consulted a pupil of Ramsay's on the matter, but was told that nothing was known of it and that it was improbable. It is interesting to have the source indicated. Whether it is useful to mention it in an elementary book is questionable. The statement in the review is quite unobjectionable and leaves the matter open.

(3) Other examiners object strongly to the use of such words as 'tip' to describe careful quantitative work, and it is specifically condemned in a report of the London Higher School Certificate examiners. Some teachers may encourage such slipshod words but most would, the reviewer thinks, not favour them.

(4) Most authors are grateful when errors of any kind are pointed out.

(5) The reviewer sees no reason to modify what was said under this head and adheres to his opinion.

(6) The statement that the mineral acids were discovered by Jabir is not accepted by the modern authorities on Arabic science, such as Ruska. The statement quoted from Holmyard is perfectly correct but has no real bearing on the matter. The point, which seems to be missed by the author, is the relation between the writings of Jabir (the authenticity of which has also been questioned) and the Latin work which goes under the name of Geber. The information in the book is based on old-fashioned sources and requires correction.

THE REVIEWER.

LIGHT OF THE NIGHT SKY AND TERRESTRIAL MAGNETISM

By D. R. BARBER
AT LICK OBSERVATORY, CALIFORNIA

ALTERNATIVE theories[1] that seek to explain the mechanism of the selective emission forming the principal component of the night-sky spectrum postulate solar excitation as the primary cause. On this premise the initial ionization of the gas molecules (O_2, N_2) that are known to exist in the terrestrial high atmosphere is effected either by direct absorption of ultra-violet radiation, or by bombardment with high-speed electrons presumably emitted from the photospheric layers.

Now it is an observed fact that the terrestrial magnetic field is, in part, due to extra-terrestrial influences of solar origin. Hence it appears logical to presume that a significant correlation should exist between the luminous activity of the night sky and solar activity. The magnitude of the latter will be reflected in the perturbations of the magnetic elements, and a measure of this perturbation will yield a reliable index of such activity. S. Chapman[2] has stressed the desirability of investigating the problem experimentally but, hitherto, attempts to reveal a connexion of this nature have not met with conspicuous success. Lord Rayleigh and H. Spencer Jones[3] find some evidence of an enhanced nocturnal luminosity on magnetically disturbed days, but their results are inconclusive.

Systematic observations of the yellow-green (5577 A.) radiation from the night sky obtained at the Lick Observatory, Mount Hamilton, California, which I have made, using a concentric-field visual photometer[4], offer experimental evidence of an intimate connexion between measures of luminous activity and those of magnetic disturbance.

Values of nocturnal luminosity over an area of sky approximately four square degrees in extent at the north celestial pole were obtained during five months in 1940 on nights when excellent photometric conditions prevailed. The observations here referred to were made at five-minute intervals, and were restricted to those hours of the night when no direct, or scattered moonlight, or twilight was visible above the horizon. The photometric measures were reduced to an arbitrary (linear) scale of luminosity. From these, mean nightly values of the luminosity L, the range of luminosity ΔL, and the luminous 'activity', that is, the product $L.\Delta L$, were computed for each epoch. The complete series of observations was examined in conjunction with the Mount Wilson magnetograph records of horizontal intensity H, which were made available for this purpose by courtesy of the Carnegie Institution of Washington.

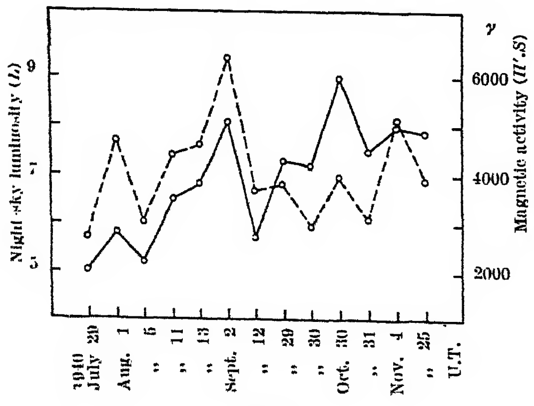

Fig. 1.

COMPARISON BETWEEN NIGHTLY VALUES OF NIGHT-SKY LUMINOSITY AT MOUNT HAMILTON (SOLID LINE) AND MEASURES OF MAGNETIC ACTIVITY AT MOUNT WILSON FOR PRECEDING DAY (BROKEN LINE).

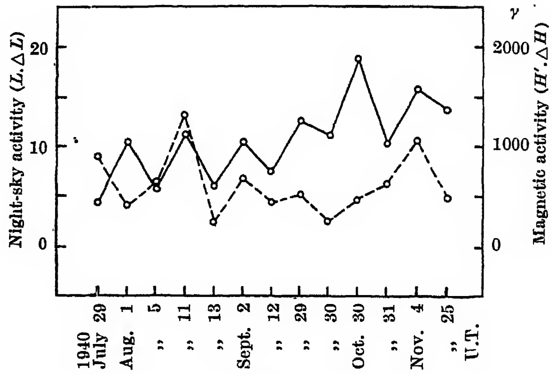

Fig. 2.

COMPARISON BETWEEN NIGHTLY VALUES OF NIGHT-SKY ACTIVITY AT MOUNT HAMILTON (SOLID LINE) AND MEASURES OF CONCURRENT MAGNETIC ACTIVITY AT MOUNT WILSON (BROKEN LINE).

The results of the analysis are exhibited graphically in Figs. 1 and 2. The comparative curves of Fig. 1 represent plots of night-sky luminosity L (full line), and magnetic activity (broken line) against epoch of observation. The magnetic activity is expressed here as the arithmetical product of the mean ordinate H', and the diurnal range S, for the twenty-four-hour period *preceding* the nocturnal observations. The correlation coefficients for the paired points from the two curves are $+ 0 \cdot 79$ for the period July 29 to September 29 U.T., and $+ 0 \cdot 31$ for all days. It will be noted that there is some divergence of the curves for the later dates: this is primarily responsible for the lower value of the coefficient r derived from the complete series. The reason for this divergence remains a matter for speculation. It may be added that a direct comparison of the nocturnal luminosity curve with that representing a plot of the diurnal variation of H—the amplitude S of which is dependent on the degree of ionization during the hours of insolation—yields also a significant, but slightly lower, positive correlation.

The foregoing comparisons involved measures of magnetic activity over a period of time antecedent to that of the night-sky observations. The paired curves of Fig. 2 exhibit a comparison between the

activity of the night-sky light, as already defined, and the *concurrent* magnetic activity, expressed as the product $H'.\Delta H$, recorded at Mount Wilson 300 miles south-east of Mount Hamilton. Although the correlation between the two curves is less pronounced, and the earlier measures form interlocking points, the point-to-point correspondence is again evident. The coefficients of correlation, referred to the same periods of time as in the previous comparison, are $+ 0 \cdot 18$ and $+ 0 \cdot 11$ respectively. The much lower values of r may, in part, be accounted for by the fact that measures of activity involve observation of the rather rapid fluctuations in sky brightness that are likely to be influenced by localized meteorological conditions. Further, the plots of magnetic activity were derived from measures of H obtained at intervals of time comparable with those of the photometric records. In the circumstances a high degree of correlation would appear improbable.

The results of the foregoing comparisons furnish evidence regarding the reality of the suspected connexion between the two geocosmic phenomena under discussion. They indicate that the level of luminosity of the night sky is determined by the degree of solar ionization established during the hours of daylight, and that the relatively frequent, irregular fluctuations of luminosity which are observed to occur during the night can be attributed, in some measure, to the same agency as that responsible for the concomitant magnetic disturbance.

The general nature of this relationship is further corroborated by the close correspondence revealed by comparisons of the seasonal and diurnal trends in nocturnal luminosity with those of magnetic activity. The results of this latter investigation are presented elsewhere[5].

Further research, using a photo-electric technique, which is now in progress, aims at an extension of the comparative analysis to measures of nocturnal radiation in other spectral regions.

SPIRITUS VITALIS

DURING the past ten years evidence has been accumulating that the reduction of carbon dioxide, a process widely thought of as unique to green plants, may actually be a characteristic of many and widespread organisms and perhaps indeed of universal distribution in living cells. Much of this evidence has been brought together by J. W. Foster, S. F. Carson and S. Ruben (*Chronica Botanica*, 6, No. 15, 337; 1941) in an instructive article under the above title and with a useful list of key references.

In addition to the well-known cases of chemosynthesis introduced by Winogradski (for example, sulphur bacteria, nitrifying bacteria) it is now recognized that some purple bacteria absorb carbon dioxide in light in the presence of sulphuretted hydrogen (Thiorhodaceæ, differing therefore from sulphur-bacteria in the need for light) or of organic compounds (Athiorhodaceæ). Similarly the organism responsible for methane production reduces carbon dioxide in the presence of hydrogen, propionic bacteria reduce carbon dioxide during the fermentation of glycerol and other substrates, and the anærobic spore former (Clostridium sp.) isolated by Wieringa in 1936 synthesizes acetic acid from carbon dioxide with gaseous hydrogen as the sole reducing agent. There has been sporadic mention of the fact that carbon dioxide is necessary in small amounts for the development of a number of heterotrophic bacteria, for yeast and for other fungi some of which can be stimulated to more rapid growth in the presence of carbon dioxide at concentrations higher than in normal air. Consideration of the facts relating to pigmented cells led van Niel to propose a generalized formula for photosynthesis:

$$2H_2A + CO_2 = (CH_2O) + H_2O + 2A,$$

the hydrogen donor being considered as water in green plants (substantiated by Ruben *et al.* in 1941 using heavy oxygen), sulphuretted hydrogen in green bacteria, sulphuretted hydrogen and other reduced sulphur compounds for purple sulphur bacteria, and an analogous formula would seem to apply to most carbon dioxide reductions by organisms. Thus *B. coli* contains an enzyme 'hydrogenlyase' which catalyses the reaction

$$HCOOH \rightarrow CO_2 + H_2.$$

Another organism catalyses the same reaction but reunites the gases to form methane under the influence of 'hydrogenase'. In this it resembles the classical methane fermentation and here, according to van Niel, the hydrogen comes from any oxidizable organic substrate acting as hydrogen donor, with the general relation

$$4H_2A + CO_2 = 4A + CH_4 + 2H_2O.$$

This and other systems are examined briefly in the review.

In the bulk of these cases the overall metabolism is such that a net uptake of carbon dioxide occurs. The situation in the case of heterotrophic organisms is complicated by the fact that a net *production* occurs. These have now been investigated using radioactive carbon, and a number of tissues and organisms of different physiological types, both plant and animal, are now known to absorb carbon dioxide. It is finally pointed out that the application of this new method to normal photosynthesis in green plants proves carbon dioxide to be absorbed in darkness, and has suggested that the first intermediate in the photosynthetic process is a large molecule (mol. wt. approx. 1,000) with a free $-$COOH and an $\alpha -$OH. This is conceived as an enzyme or its prosthetic group and suggests that the following reaction occurs:

$$RH + CO_2 \rightarrow RCOOH:$$
$$RCOOH + H_2O + h\nu \rightarrow RCH_2OH + O_2.$$

RCH_2OH adds another carbon dioxide and the process continues until long carbohydrate chains are built up and split off as starch or soluble sugars.

GRASS AS HUMAN FOOD

IN normal agricultural economy the main role of the farm animal is to convert coarse vegetable foodstuffs into palatable and readily digested meat and dairy products. In war-time the value of this function must be reviewed in relation to the exigencies of the shipping situation, and the gain in quality in foodstuffs of animal origin must be balanced against the great loss in quantity which must inevitably occur during the conversion. Some peace-time practices, such as the liberal use of wheat in feeding poultry, are obviously out of place during war-time. It is difficult, however, to forecast what degree of success could be attained in a frontal attack on the position of the farm animal, in which the aim would be to make part of the vast food resources of green pasture directly available for human consumption.

The main objection to the use of grass as a major component of the human diet lies in its high content of cellulose. Since the water content is high, a large bulk would have to be taken to make a significant contribution to the daily calorie requirement, and the undigested residue would prove an intolerable strain on the capabilities of the human intestine. Two distinct possibilities for the use of grass may, however, be recognized. (1) The manufacture of concentrates, free from cellulose, which might be eaten freely as substitutes for meat and cheese. Most of the vitamins would presumably be separated during this procedure, and could be worked up as a by-product. (2) The direct consumption, in salads or otherwise, of small amounts of young tender herbage. This dietary innovation would be valued as a source of vitamins, rather than as a serious contribution to the protein or energy requirements of the body.

In a pamphlet "Eating for Victory", a sequel to "Grass for All", Mr. J. R. B. Branson describes his personal experience of a vegetarian diet containing moderate amounts of fresh or dried grass (Branson's Publications, Headley Mill Farm, Bordon, Hants. 4*d*.). At the ripe age of sixty-eight, he reports a remarkable physical and spiritual rejuvenation, and describes the performance of tests of physical endurance which were possibly more arduous than scientific. In his opinion the beneficial properties of grass may be related to its chlorophyll content, and reference is made to the experiments of Prof. Buergi of the University of Berne. It may be recalled that this work is frequently quoted in advertisements in the popular Press in support of the supposed rejuvenating properties of a commercial preparation of this pigment.

While it is very doubtful indeed whether authentic medical opinion would support the view that chlorophyll has any real therapeutic virtue, it is possible that Mr. Branson may have benefited from the high vitamin content of his unusual diet. To those who might be persuaded to take advantage of the numerous recipes for the use of grass which he has propounded, we would repeat with emphasis his own advice of *festina lente*. Even small amounts of grass might prove injurious to digestive organs less robust than those of Mr. Branson. The injudicious ingestion of amounts made possible by the zeal of an ardent food reformer might easily give rise to intestinal obstruction, which would certainly be serious and possibly fatal.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

SATURDAY, JULY 19

ROYAL METEOROLOGICAL SOCIETY (joint meeting with the London Branch of the Institute of Physics) (at 49 Cromwell Road, London, S.W.7), at 2.30 p.m.—Discussion on Thunderstorm Problems.

FRIDAY, JULY 25

PHYSICAL SOCIETY (at the Science Museum, Exhibition Road, London, S.W.7), at 5 p.m.—Prof. Sydney Chapman, F.R.S.: "Chree and his Work on Geomagnetism; Geomagnetic Time Relationships; and The Future of World Magnetic Surveying" (First Charles Chree Address).*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

FIVE ASSISTANTS (MALE OR FEMALE) IN AGRICULTURAL ECONOMICS, ONE (MALE OR FEMALE) ASSISTANT AGRICULTURAL ANALYST and TWO ASSISTANT FIELD MEN (MALE OR FEMALE)—The Agricultural Officer, Department of Agriculture and Horticulture, The University, Bristol (July 26).

LECTURER IN CHEMISTRY (GRADE IIA)—The Secretary, The University, Edmund Street, Birmingham 3 (July 31).

ASSISTANT ENGINEER TO THE MUNICIPAL COMMISSIONERS OF GEORGE TOWN, PENANG—Messrs. Peirce and Williams, 1 Victoria Street, London, S.W.1 (July 31).

PRINCIPAL of the Oldham Municipal Technical College—The Director of Education, Education Offices, Oldham (August 9).

DOMESTIC SCIENCE MISTRESS of the Girls' Intermediate School, Omdurman—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, London, S.W.1 (endorsed 'Girls' Intermediate School).

NATURE

SATURDAY
JULY 26, 1941

THE FRATERNITY OF SCIENCE

THE early years of the twentieth century saw a recrudescence of the movement towards international intercourse in science. The natural philosophers of previous centuries, so far as they were free to carry on their studies, enjoyed a peculiar individual licence to visit and maintain communication with their brethren in other lands. With the growth of science itself, those associated with it began to band themselves together for the more frequent discussion of the many topics in which they were interested, and it was natural that such groups, at first local, should with the improvement of communications become national in scope. The national bodies continued to maintain a limited amount of intercourse by the exchange of publications and by the election of distinguished men of science as foreign members, but this in turn became inadequate to meet the needs of the rising tempo of scientific discovery and its applications. Thus were born the international associations, with regular meetings held at intervals of a year or more, attended by individuals and delegate bodies, and with international secretariats to transact their business during the intervals between successive meetings.

Into this healthily growing international intercourse of scientific men was injected the Nazi claim for 'Aryan science' and for 'Nordic superiority' in science as in other fields, followed by the exclusion from the calling of science of all who could not prove their purity of 'Nordic blood'. The result is well known to readers of NATURE. Everyone can recall how, in his own particular field, first one, then another distinguished figure, sometimes men of international repute, was forced to leave Germany, often in a state bordering on destitution.

It is worth while examining again the beginnings of this state of affairs. Dr. Julian Huxley traces in brief but telling fashion the rise and decay of science in Germany in a recent pamphlet "Argument of Blood"*. From the fifteenth century onward, the Germanic peoples have made noteworthy contributions to science ; as examples of

* Argument of Blood : the Advancement of Science. By Julian Huxley. (Macmillan War Pamphlets, No. 11.) Pp. 48. (London : Macmillan and Co., Ltd., 1941.) 3*d*. net.

outstanding men Dr. Huxley mentions Albrecht Dürer, Kepler, von Guericke, Leibniz, Goethe, Fraunhofer, Gauss, of the earlier period, and Liebig, Bunsen, Kirchhoff, Abbe, Koch, Ehrlich, Hertz, and Caro, Graebe and Libermann of more recent times. Nevertheless, science was later in achieving organized form in Germany than in England, France or Italy. With the opening of the nineteenth century, however, the modern German university system began to develop under the ægis, and with the aid of, the State, and the attention given to science led, by the middle of the century, to the German university institutions becoming the accepted homes for schools of scientific research built up by the university professors, to which flocked students from other parts of Europe and from the United States. All this time, however, the State retained its hold on the universities, and was able to ensure that research did not lose touch with industrial development.

Incidentally, Dr. Huxley points out that a very substantial part was taken by Jews in this development of science and its applications. Although they formed only about 1 per cent of the population, it is estimated that they have been responsible for some 25 per cent of significant German contributions to science. German anti-Jewish outbursts, Dr. Huxley suggests, may thus be in part a symptom of an inferiority complex.

Their mode of development will account for the difference in outlook between German university institutions and those of Great Britain. The State has always exercised a degree of control which, with the rise of National Socialism, enabled the Nazi Party quickly to abolish all freedom of study. Dr. Huxley refers in particular to events in the Universities of Heidelberg and Göttingen. By 1936, he says, all serious instruction in philosophy at Heidelberg had ceased, and nearly half the staff in that faculty had been dismissed; appointments were being made on political grounds. At Göttingen similar changes were made; within a year, nearly a quarter of the University staff had been dismissed.

Such drastic changes in the university system of Germany were bound to have repercussions on the output of scientific research as regards both quality and quantity. The former is difficult to assess, but the correspondence columns of NATURE will serve as a criterion of the latter. Here it was noticeable that the number of original contributions to science coming from German institutions quickly decreased: allowance must, however, be made for the fact that support in NATURE for a policy of intellectual freedom had brought the journal into disfavour. Dr. Huxley points out that the deterioration in quality has been most marked in mathematics, physics and pure biology; whereas in a subject of direct military value, such as aircraft engineering, a number of valuable contributions to knowledge has been made.

Both staff and students were affected by the changes imposed by the Nazi regime. Although it is difficult to obtain statistics relating to university education in the years immediately preceding the War, it is known from the records of societies assisting displaced intellectuals that nearly 2,000 university teachers were dismissed; many posts were filled with 'safe' Party men, but others were discontinued. As a result, the university teacher lost that security of tenure which hitherto had left him free to pursue his investigations and to teach the truth as he found it without regard to political considerations. The effects on the student body were even more striking. The number of students was reduced to nearly one half of what it was before the Nazis assumed power. Military and semi-military studies were given greater prominence, while the course for medical students was reduced by two years. Another innovation, doubtless made in pursuance of the search for 'leaders' who would be both docile to central Nazi control and also sufficiently immature to be fanatical in their adherence to the new regime, was to appoint student bodies under Party guidance and led by students who in some cases were placed outside the jurisdiction of the university authorities. Normal university life was deliberately undermined.

Apart from these direct attacks on learning, one of the most sinister undertakings of the Nazis has been the deliberate distortion of truth, undertaken with the view of providing a seemingly scientific basis for National Socialist ideology. Dr. Huxley very fittingly deals with the so-called 'racial biology', which is taught from the elementary schools upwards. By a profusion of literature, by lectures and by all the guile of propaganda, the superiority of the 'Aryan', 'Nordic' or 'German' race has been drummed into the minds of a generation who have never been allowed to hear its fallacies discussed. It will be a difficult but essential task to undo this work in the years to come.

With all this coercion and suppression of scientific effort, it is not apparent at first glance why Nazi Germany has been able to make such efficient use of scientific and engineering developments for waging war. The answer Dr. Huxley gives—and it will be generally accepted—is that Nazi success has been based on the large store of technical knowledge and the numerous skilled men trained on scientific principles still remaining in Germany; time will reduce their number and make their training out of date.

So much for effects within Germany itself of

the suppression of freedom of learning. Sir Richard Gregory, president for the duration of the War of the British Association, and formerly for many years editor of NATURE, takes up the tale at this point in "Science in Chains"*, and voices the feelings of men of science outside Germany, who have observed, at first with concern and later with horror, the cramping restrictions imposed on research and the barbaric discipline which have followed in the wake of Nazism.

An early hint of the attitude of the Nazi Party to scientific intercourse was seen in 1934 at the meeting in Berne of the Astronomische Gesellschaft, a body which, though German in origin, is strongly international in character. One of the secretaries was a Jew, and the German delegates to the meeting were ordered to exclude him, and any other Jewish astronomer, from office. The attempt failed, but it conveyed a warning as to the character of German delegations which would attend scientific meetings outside Germany. Indeed, in 1935, by order of the Minister of Propaganda, all representation at congresses, inside or outside Germany, was put under the control of a Science Congress Centre, on the specious excuse as regards foreign travel that lack of foreign currency made such centralization necessary. Further, all who went abroad for purposes of study or to give lectures were required to report themselves to the local German representative and to the Foreign Organization of the Nazi Party. The object of these regulations was immediately obvious: they were to ensure that only politically 'safe' spokesmen would be allowed to interpret scientific developments in Germany to the outside world. Under such conditions there can be no adequate exchange of scientific views, and science degenerates into an instrument of national aggrandizement.

This intellectual blight, as Sir Richard Gregory terms it, has descended on every country which has come under Nazi control. With the occupation of Czechoslovakia in 1939, all scientific work had to cease; institutes were closed, and equipment was destroyed or transferred to Germany. Similar measures were taken in Poland, and some of the ancient universities of Holland have suffered. There should be no need to enlarge upon such instances of Nazi repression as it affects science, for many have been recorded in NATURE during the past two years.

What has been the reaction of the world of science to this reversal of the whole trend of scientific intercourse? An early movement was the formation of a body, now known as the Society for the Protection of Science and Learning, to help intellectual workers who have been deprived of their means of livelihood for racial or political reasons. This body has done magnificent work in providing for many such refugees the opportunity of continuing their vocation, and thus has preserved for civilization the intellectual powers of a considerable body of men. Another effect, perhaps slow to gather strength, was the appearance of protests in the scientific Press; these protests were at first cautious, for scientific men did not care to risk the charge of interfering with what might at first appear to be the internal affairs of another country. One result of such protests was, as readers of NATURE will recall, that this journal was "excluded from general use in scientific libraries" in Germany; it will be noted that the journal was not entirely banned, for apparently it was still of service, and incidentally, as Sir Richard Gregory points out, German publishers continued, until the outbreak of war, to send scientific works to NATURE and other responsible British journals, confident that they would be justly appraised and the reviews accepted by scientific colleagues all over the world.

Another stage in the growing volume of protest was marked by a resolution passed in 1938 by the American Association for the Advancement of Science, in which the democratic principles of science and the need for intellectual freedom in research were strongly urged. "We regard the suppression of thought and of its free expression as a major crime against civilization itself." Since then, the American Association has asked the British Association to collaborate in framing a charter of democracy on scientific principles, and as a first step towards such collaboration, the Division for the Social and International Relations of Science of the British Association has formulated a statement of the democratic fellowship of science.

Freedom of thought and freedom of communication between the scientific workers of all countries are essential to the progress of humanity. Any political system which challenges these cardinal principles threatens the very life-blood of science; whatever temporary successes it may achieve by tapping existing reservoirs of knowledge and skill, it contains within itself the seeds of decay. Sir Richard Gregory rightly says: "Science would be false to its tradition if it failed to protest against such criminal assaults on the human mind. Its spirit cannot be confined within any national or racial boundaries, and its service cannot be monopolised by any single country, without debasing the principles for which it has always stood. To make race, political convictions, or religious faith, barriers to the pursuit of natural knowledge, means that science in Nazi Germany loses its soul for the purpose of gaining the world."

INDUSTRIAL CHEMICAL ANALYSIS

Lunge and Keane's Technical Methods of Chemical Analysis

Second edition, edited by Dr. Charles A. Keane and Dr. P. C. L. Thorne. Vol. 4. Pp. xv+963. (London and Edinburgh: Gurney and Jackson, 1940.) 84s. net.

IN the years immediately succeeding the War of 1914–18, British chemical industry underwent a renaissance the chief features of which included the intensification of research both by individual firms and by the newly constituted research associations, the rationalization of industry, and the formation of merged companies. In many cases products and processes of manufacture were standardized. Methods of testing were reviewed and modernized and new analytical technique developed to keep pace with the ever-increasing range of new products.

Many of these new developments are reflected in the new edition of Lunge and Keane's standard work on "Technical Methods of Chemical Analysis", the fourth volume of which deals in two large sections with textiles and textile chemistry and with coal tar and tar products; there are, in addition, relatively smaller but equally important sections on coal gas, ammoniacal liquor, explosives, matches and fireworks and on calcium carbide and acetylene. It is essential in a work of this description that the subject-matter should be beyond reproach, and the authenticity of the details in Vol. 4 is guaranteed by the high professional status of the authors of the various sections.

In present circumstances, two of the smaller sections, namely those on explosives and on calcium carbide and acetylene, make a most opportune appearance. The manufacture of explosives must always remain a highly specialized industry in which the most extreme precautions are necessary to ensure not only the safety of the workers but also the stability of the manufactured product. In normal times this manufacture is carried out by a relatively small number of skilled technicians, and the use of explosive material is largely restricted to the engineering profession. War conditions, however, necessitate a very large increase in the number of those engaged on the manufacture, handling and safe storage of these dangerous materials, and the detailed tests described by Prof. O'Reilly not only of the raw materials used but also of the finished products will be of the utmost value to both the technical chemist and the authorities on whom rests the responsibility for the operation of adequate safety measures.

Almost all gas welding operations require acetylene, for which calcium carbide is the necessary basis. A very large expansion in the manufacture of this important industrial gas takes place therefore during times of war, when all branches of engineering operate under high pressure. The details of the tests necessary in the production of acetylene come from the authoritative pen of Mr. C. Coulson Smith, of the British Oxygen Co., Ltd., which hitherto has been almost wholly responsible for this manufacture in Great Britain. The author does not concern himself primarily with any test relative to the production of carbide but devotes himself to those tests required for the examination of the finished carbide and of the acetylene derived therefrom. Particular attention is given to the tests for phosphorus impurities, which are suspected of being the cause of some acetylene explosions. These detailed tests are most timely in view of the increased number of chemists, engineers and other technicians now engaged in this important industry, and assume greater significance in view of the industrial importance of acetylene derivatives such as cyanamide, thiourea, melamine and the vinyl polymers.

The staff of the South Metropolitan Gas Co. are responsible, through Mr. H. D. Greenwood and Mr. P. Parrish respectively, for the sections on coal gas and ammoniacal liquor and ammonium salts. The description of modern methods of analysis in the coal gas industry is noteworthy for the information on the evaluation of refractories and the methods of control during carbonization. As an illustration of the original work always proceeding in the laboratories of the gas undertakings, there is a very clear account of the comparatively recent brilliant research work carried out by H. Hollings and his colleagues of the Gas Light and Coke Company leading to the elimination of gum formation in coal gas.

Many of the new developments in the British chemical industry noted at the outset of this review are to be found in the history of the coal tar industry during the past twenty years. Of all the raw materials of industry, coal tar occupies a unique position, being on one hand a by-product of one major industry—coal carbonization—and on the other the starting material for a whole range of other important manufactures. The general

economics of this raw material are based on the profitable marketing of several well-known fractions such as benzole, naphthas, creosote, cresylic acid, anthracene oil and pitch. To these must be added a surprisingly small list of pure constituents, chiefly benzene, toluene, naphthalene and anthracene, together with phenol, the three cresols and pyridine. Although it was possible for any organization, deriving its tar from a given source, almost to standardize its products, there was obviously much variation in the fractions produced by different organizations, and discrepancies were accentuated by the introduction of new varieties of tar, in particular vertical retort tar. It was realized, therefore, shortly after the War of 1914–18, that the time was ripe for standardization of products throughout the tar industry. Rationalization was carried out by the formation of several large groups, which together with the already powerful tar organizations of the metropolitan gas undertakings, formed the Association of Tar Distillers. This Association, working through several expert committees, proceeded to review and select satisfactory tests for tar products, finally publishing a volume entitled "Standard Methods for Testing Tar and its Products", to the mutual benefit of producers and consumers. The work of these committees provided a shining example of the pooling of general knowledge, and "Standard Methods" crystallizes the accumulated experience of many organizations over a long period.

The 1938 edition of "Standard Methods" forms the basis of the large section on coal tar and tar products contributed to Lunge and Keane's treatise by Mr. A. McCulloch and Mr. R. Murdin Drake. The authors, however, have not restricted themselves to the British standards, but also include some of those accepted in the United States of America and in some cases in Germany. This section, therefore, is most comprehensive and includes, in addition to the technical tests, much general information with respect to the production and utilization of tar and tar products. It is unusual but useful to find descriptions of the tests employed, for example, of the disinfectants and insecticides made from tar products. The authors have also drawn on the results of research carried out, notably by the National Benzole Association and the British Road Tar Association. This latter organization is responsible for much original investigation in the evaluation and improvement of prepared tars, particularly for road construction work, which absorbs by far the largest proportion of the tar produced in Great Britain.

This comprehensive section represents the most up-to-date evaluation of coal tar and its products to be found in any book and will form the standard reference work for all those engaged either in the distillation or in utilization of tar products. Whereas the reader of this section cannot fail to be impressed by the very thorough manner in which the tar industry has standardized the tests for its products, he may on reflection wonder why so few of the many constituents of this material are isolated in a pure condition. Admittedly, the entities described are those for which there is a ready demand, but one hopes that this well-organized industry will develop technique whereby lesser-known but potentially valuable components such as β-methyl naphthalene, higher aromatic hydrocarbons such as pyrene, together with the individual xylenols, or even higher phenols may be isolated and their uses developed.

Of the many trade research associations which were initiated in collaboration with the Department of Scientific and Industrial Research, two of the most successful were those connected with the cotton and wool industries. The results of investigations carried out by these organizations were quickly adopted by industry, with the result that many new processes for the treatment and testing of textiles were developed. How widespread has been the expansion in the technique of textile chemistry may be judged by the fact that no less than 280 pages of the new edition of Lunge and Keane, as compared with only 140 in the old edition, are devoted to the description of the various tests now applied in the manufacture and examination of textile fabrics, including the rayons, which have been wholly developed since the period covered by the first edition of this treatise.

The whole section on textiles and textile chemistry has been prepared under the general supervision of Mr. J. M. Preston, of the College of Technology, Manchester, the sub-sections having been prepared by a team of experts. A wide range of information hitherto not to be found within the bounds of one book has been collected, arranged and presented in the logical sequence of: physical and chemical tests of textile fibres and fabrics, tests for dyestuffs, auxiliaries and detergents used in the industry and finally tests for finishes and their defects.

Few, except those directly engaged in the industry, can be aware of the many tests applied to ensure that high standard now expected of and maintained by the textile industry. Microscopical, chemical and mechanical tests are regularly used throughout all the stages of aggregation met with during manufacture, from that of the single fibre to that obtaining in the finished article. In addition, the auxiliaries such as wetting agents and soaps are subjected to rigorous examination, while the testing of dyestuffs, particularly as regards fastness, forms a whole field of chemical technology

itself. Each of these series of tests requires a highly skilled and specialized staff to whom the details of tests applied in the branches of the industry other than their own will be most useful. To those outside the textile industry, the last subsection on the examination of textiles after finishing probably holds most interest. In the past twenty years permanence of colour and finish have been greatly improved and many new finishes introduced, eighteen of which are described in this subsection. As an example, there is the development of the use of synthetic resins, particularly urea-formaldehyde, to yield a fabric with increased resistance to creasing, and the use of formaldehyde in conjunction with an aliphatic amide to produce resistance to wetting.

A book on technical methods of analysis might be considered by the superficial inquirer to furnish rather arid reading except to those experts directly interested, but in this volume the reader will find much of the romance of chemical industry. Many of the new processes and products which have now become familiar names are here described in an accurate, scientific and readable manner to whet the interest and excite the imagination of the reader. Of primary interest to technicians, and written with the object of defining the various tests applied in the selected industries, the book forms a mirror of the achievements of these industries during the past thirty years, and shows once more that there is no finality in chemistry.

D. D. PRATT.

PREPARATION OF ORES FOR METALLURGICAL TREATMENT

(1) Textbook of Ore Dressing

By Prof. Robert H. Richards and Prof. Charles E. Locke, assisted by Prof. Reinhardt Schuhmann, Jr. Third edition, completely revised and rewritten. Pp. xiii+608. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 36s.

(2) Principles of Mineral Dressing

By Prof. A. M. Gaudin. Pp. xi+554. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 33s.

THE maintenance of the present standard of living of civilized man is dependent upon an adequate supply of metals, without which conditions would return to those of the Stone Age. The production and preparation of food, clothing, transport and other necessities all depend fundamentally upon the provision of the requisite tools. These tools are largely made from metals, and to cover wastage and also expansion in the use of mechanical aids fresh supplies have to be made available continuously.

The use of non-ferrous metal in the arts has so increased in the last hundred years that it is unlikely that there are undiscovered any rich, readily accessible sources from which losses can be made good. Luckily the supplies of iron and coal are still more than adequate to meet all needs in normal times. But man cannot live by iron alone, and other metals have to be provided.

The mineral deposits that are being worked to-day, as distinct from those worked in earlier times, nearly always consist of complicated mixtures of valuable ores and worthless gangue which have to be separated. Further, the individual ores have to be segregated from each other and collected in the form of concentrates. This process is known to mining and metallurgical engineers as 'dressing', a word which occurs in the titles of both books under review.

The term 'dressing' in each case is used to indicate the separation by physical means as distinct from metallurgical treatment in which chemical reactions are employed. Many and varied advances in science and engineering are employed in modern dressing, and in a single book it is impossible to discuss every known principle and practice in use.

It is interesting to recall that up to thirty years ago simple processing by water concentration accounted for 90 per cent of the world's output of non-ferrous metals, whereas to-day, except for alluvial workings, it accounts for less than 10 per cent. Its place has been taken by the froth flotation process: the separation of minerals from one another in a froth by virtue of difference in their surface tension. Up to 1924 the main application of the frothing process consisted of bulk flotation of sulphides in an acid circuit using oils of various kinds as reagents, whereas to-day, selective or differential flotation is the common practice using organic or inorganic chemicals in an alkaline circuit. No solution has, however, yet been obtained to the problem of floating oxides such as cassiterite, which would prove a boon to the Cornish mining industry.

The publication of two new text-books by well-known writers on the subject is always a matter

of interest, and there is an additional piquancy when it is realized that the authors are both members of the Faculty of Mining Engineering at the same institution at Massachusetts.

The method of treatment of the subject-matter is widely different and yet the two books might be considered complementary. Locke's text-book is a welcome and long overdue revision of Richard's standard work, whereas Gaudin's is new and is compiled, as he says, largely from his lecture notes and research activities. It is impossible for the two books not to overlap, but in general it can be said that they cater for different types of readers. Locke will appeal to the works operator, the man who wants to know *how* to do something, whereas Gaudin will be of more assistance to those who wish to know primarily *why* a process works. Broadly, one describes modern practice and the other the principles underlying modern practice, but includes an exceptionally good bibliography of the subject.

Both books follow the conventional lay-out in that, chapter by chapter, they discuss the machines used in each stage of a mineral dressing plant, only differing in the emphasis placed upon the various items.

Thus, stage by stage, they cover the processes by which the crude product of a mine is broken to a sufficient degree of fineness to release the valuable ore from unwanted minerals and then describe various methods employed to collect it.

Both books should be in the library of all metalliferous mining engineers and, in the case of Locke, of coal miners also, because one chapter is devoted to a discussion of the equally important subject of coal cleaning. J. A. S. RITSON.

A GENERALIZATION OF ABELIAN INTEGRALS

The Theory and Applications of Harmonic Integrals
By Prof. W. V. D. Hodge. Pp. ix+281. (Cambridge: At the University Press, 1941.) 12*s*. net.

PROF. HODGE's work on this subject has long been awaited by his colleagues, and will be generally welcomed by them, though perhaps with mixed feelings when its difficulty is encountered. His lectures and papers have already given some idea of the scope the work would have, as well as of the origin of the line of research of which this book is the first important monument. It is in effect an attempt to generalize in a very wide way that aspect of the study of functions (such as Abelian integrals) on a Riemann surface which consists in treating the real and imaginary parts separately, and adjoining to the integrability condition a second differential condition which ensures that the two functions considered are in fact the real and imaginary parts of an analytic function. (This latter we may call the orthogonality condition.) The place of the Riemann surface is taken by a 'Riemannian manifold' of any number of dimensions; this is continuous and has ordinary differential geometry in the small, with metric, affine connexion, and Riemann-Christoffel tensor; while in the large it is a two-sided or orientable space, to which the ordinary combinatory topology applies, with Betti numbers, torsions and intersection matrices.

The first chapter is devoted to recapitulation of these two theories. The second develops the idea of a p-fold integral, and the differential form associated with it, and includes the generalization of Green's and Stokes's theorems, in virtue of which we have first-order differential conditions for integrability, to ensure that the value or 'period' of the integral over homologous cycles is the same; the chapter ends with de Rahm's proof of the existence of an integral with assigned periods on all linearly independent p-cycles. In this no use is made of the metric; but the next chapter defines a harmonic integral as one which satisfies not only the integrability conditions, but also a second set of first-order differential conditions, depending on the metric, and analogous to the orthogonality condition in the simple case; the coefficients in a form which satisfies both conditions may be compared to the components of a vector the curl and divergence of which both vanish. Hodge's own proof then follows of the existence of a unique harmonic integral having assigned periods.

The remaining two chapters are devoted to the applications of the foregoing theory to algebraic geometry, and to the theory of continuous groups. The former (presumably the *raison d'être* of the whole investigation) are, as the author says, isolated, and may at first sight appear somewhat meagre. The bulk of the labour in this chapter is devoted to sorting out which of the harmonic integrals are in fact the real and imaginary parts of algebraic integrals; the metric in the Riemannian manifold of $2m$ dimensions (which represents the complex points of an m-dimensional algebraic variety just as the Riemann surface does those of an algebraic curve) is not invariant, and its possible trans-

formations are not even confined to be conformal, as in the case $m=1$; so that the theory of harmonic integrals contains, in a sense, a good deal of lumber which must be cleared away before the genuine applications to obtain algebraic-geometric results can be made. The definition of the geometric genus in terms of the signature of an intersection matrix, published some years ago for surfaces and here generalized, is however a triumph which would have justified a far more laborious analysis, even had it been the only result; and the conditions, in terms of vanishing of periods, for a cycle to be algebraic (that is, to be the image on the Riemannian of some algebraic sub-variety on the original variety), though apparently not completely worked out as regards their sufficiency, look as if they might lead to results of great value. The theory is of course in its infancy, and it is hard to say yet how far it may take us; its chief lack so far, if it is to achieve a comparable power and importance with the classical theory for curves, seems to be anything like a generalization of Abel's theorem; and it is hard to see what form such a result could be expected to take. The applications to continuous groups seem to consist mainly of new proofs of known results, but here again it is early to say what may be achieved.

The whole book is exceedingly difficult to read—a difficulty which is partly inherent in the subject, but which one feels also is somewhat characteristic of the author. The style is very dry and severe; the summaries of previous work are too brief and formal to be readily understood unless the reader is already fairly familiar with the work in question; little time is spared for pointing out the purpose of the steps taken, or of the definitions introduced; and the notation (which is necessarily very intricate) has not always been selected with sufficient care to avoid confusion—thus on p. 160 i is in one equation a dummy suffix over which summation takes place, and the square root of -1, and there are other pitfalls of the same kind, though less glaring. The printing on the other hand seems admirable, and in all that complicated jungle of formulæ I have not detected one misprint. PATRICK DU VAL.

STEAM, AIR AND GAS POWER

Steam, Air and Gas Power
By Prof. William H. Severns and Prof. Howard E. Degler. Third edition. Pp. vii+511. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 24*s*. net.

WHEN a book such as this has reached its third edition it may be taken for granted that it possesses in high measure those qualities which go to the making of a standard work. Progress in heat engines during recent years has been considerable, but provided the method of exposition of the fundamental principles is sound and the attitude of the author to his subject is a correct one, the main structure of the work will readily carry such new developments, either in theory or in practice, as take place between one edition and another. To this category then it may be said that the present book belongs, for while in large measure keeping pace with progress in heat-power engineering it retains the excellent mode of presentation which has characterized its earlier editions.

Some developments, however, have not received the attention they deserve. In the chapter on steam generators, mention is made of high pressure and of critical pressure steam generation, but there is no reference to the La Mont and Loeffler boilers, which are now fully established types. Their respective principles of operation and details of construction are essential to the present-day student of steam power, to which it may be said that the book gives a disproportionately large space.

Dealing first with general principles, the authors pass on to describe and elucidate the extensive range of equipment which goes to form a complete steam plant. Feed-water, its treatment and heating, chimneys, draught and fans, reciprocating engines and turbines, condensers and pumps are adequately dealt with, and there is a useful chapter on steam-engine power and economy.

Air compression, compressors and engines receive treatment compatible with the importance of the use of air as a source of power in such special cases as in deep mines, where it gives three advantages—its transmission for long distances without great loss, the cooling effect of its exhaust and its help in ventilation. It can scarcely be said, however, that the internal combustion engine has been dealt with as fully as its importance and variety deserve. Apart, however, from this criticism it should be pointed out that the theoretical and practical aspects of this section of the subject have been excellently presented, and the student will receive a good grounding, particularly in the fuels available and their combustion.

An Introduction to Astronomy

By Prof. Robert H. Baker. Second edition. Pp. viii+315. (New York: D. Van Nostrand Co.; London: Macmillan and Co., Ltd., 1940.) 12*s.* 6*d.* net.

THE first edition of this work appeared in 1935, and there have been two reprints since. The second edition follows the general plan of the earlier edition, but a few minor alterations have been made to clarify certain points and various new features have been introduced to bring the work into line with astronomical progress. Two chapters, "The Galactic System" and "The Exterior Systems", have been rewritten owing to the recent rapid developments in these spheres, and of course Satellites X and XI are now included among Jupiter's satellites.

The book commences with the usual aspects of the earth and the sky and then deals with the solar system, the stars, nebulæ and galactic systems. Chapter v contains an excellent description of the constellations with a number of maps and charts which will prove very helpful to those who are commencing a study of the stars in the different seasons. A very important feature of the work is the list of questions which are given at the end of each chapter. These have a direct bearing on the subject dealt with in the chapter and they will make students realize that careful reading is necessary if the text is to be thoroughly understood. Probably many will find it expedient to re-read each chapter to answer the questions satisfactorily, and this will ensure a good foundation in the various branches which are considered. The large number of diagrams and photographs adds considerably to the usefulness of this book.

M. D.

The Francis Walker Types of Trichoptera in the British Museum

Re-described and figured by Dr. Cornelius Betten and Martin E. Mosely. Pp. x+248. (London: British Museum [Natural History], 1940.) 15*s.*

THE descriptions of Trichoptera or caddis flies, made by Francis Walker nearly a hundred years ago, have proved quite inadequate guides to their recognition. It has become increasingly difficult with the lapse of time to associate Walker's descriptions with species now established upon modern conceptions involving the use of more fundamental characters than colour, wing-pattern and the like. Walker's descriptions, however, have formed the basis for all subsequent work on American Trichoptera, since very few of the species had, in his day, been previously named. With the growth of subsequent knowledge much confusion of synonymy has resulted, and the joint authors of this work have made use of their opportunity to clarify the position for the future. They have re-described not only all the North American species, which occupy the greater part of the volume, but have also done likewise for all other recognizable Walkerian species of the order. Accompanying the descriptions are many excellent figures of the genitalia, and of the venation in cases where needed. The work has been well carried out by authors and publishers alike.

Fundamentals of Photography

With Laboratory Experiments. By Prof. Paul E. Boucher. Pp. xi+304+lii. (London: Chapman and Hall, Ltd., 1941.) 16*s.* net.

THIS book is another welcome piece of evidence of the growth of systematic teaching of photography in universities of the United States. It concentrates on the need for exact knowledge of the technique of photography, which requires experimental work as well as reading. The treatment is best illustrated by the author's definition of a good photograph as one which gives correct tone reproduction. The pictorial side is, however, equally fundamental, and a considerable proportion of students taking such a course will apply their knowledge later to work in which this plays an important part. However, the pictorial part must be largely self-taught and, if correct technique is not learned first, the odds are that it never will be.

The book loses some coherence by its order and arrangement. The camera is discussed before lenses and image formation. Developers are dealt with in Chapter ii; development in Chapter vii and again separately for negatives, contact prints, enlargements and lantern slides. The experimental section is excellent and forms a serious investigation of how photography works. It will probably be many years before any university in Great Britain provides the apparatus and facilities for such a course.

The book will then be valuable as a text-book for both teachers and students. There are few errors, but aberrations are described as 'defects in lenses' and the greater tone range made possible by slide projection is explained incorrectly. Reflex cameras are said to be popular among pressmen; the contrary is true in Great Britain and most users of reflexes are agreed that they are unsuited to speed work. The book is reasonably priced but the illustration is poor.

A. S. C. L.

The Statesman's Year-Book

Statistical and Historical Annual of the States of the World for the Year 1941. Edited by Dr. M. Epstein. Seventy-eighth annual publication: revised after Official Returns. Pp. xxxvi+1487. (London: Macmillan and Co., Ltd., 1941.) 20*s.* net.

IN spite of obvious difficulties this valuable annual makes its usual appearance and has not shrunk in size. The States of Europe and the rest of the world appear as they were before the War, and in those that have been the victims of Nazi onslaught statistics have to be confined to an earlier year than last. For the rest the figures have been revised so far as official returns permit, and the book presents a summary of current prevailing political and economic conditions for most of the world. The introductory tables of world production of various commodities are most useful. Two coloured maps show respectively naval and air-bases leased by Great Britain to the United States and the boundaries of Rumania as they were up to September 1940. It is noteworthy that the price of the volume has not been increased.

FUNGI IN RELATION TO MAN*

By Dr. J. Ramsbottom, O.B.E.,
British Museum (Natural History)

Fungi as Food

MOST people in Great Britain would classify the numerous fungi of our woods and fields into two groups, the first including one species, the mushroom (*Psalliota campestris*) which is edible, the other including the rest which are called toadstools and are labelled poisonous. Those who have eaten abroad with a true spirit of gastronomic adventure know that certain toadstools make an attractive dish and even in London continue to sample cèpes (various species of Boletus), morel, chanterelle and truffle. This list, however, can be much extended, and forty or fifty species are far more delicate in flavour than the field mushroom of which, moreover, certain of the wild forms are much superior to those usually cultivated. Formerly, several species were sold in Covent Garden market, and blewits, blue-leg or blue stalks (*Tricholoma personatum*) is still sold in the north-east, midlands and west, though round about Berwick-on-Tweed it is now bought by dyers for the extracting of a blue dye, the price offered being two shillings a stone; it would be wiser to eat them than to sell them at this price.

In these days of war, no one could accuse our diet of lacking experiment. Even so, if one suggested that toadstools might be added, there would probably be an outcry about the great danger of poisoning. The fact, however, is that very few of those that anyone would think of cooking are even suspect. But one wholesome-looking species, *Amanita phalloides*, is not only deadly poisonous, but also causes intensive and extensive agonies. One or two allied species such as *Amanita mappa* are usually considered dangerous, but it may be that there has been confusion in identity. The best-known poisonous toadstool is the fly agaric (*Amanita muscaria*) with its scarlet, white-spotted cap, which makes it the most pictured and modelled of all fungi. Here the effects are not deadly though they are severe. The remaining poisonous fungi which grow in Great Britain can be counted on one's fingers and their characters could be learned by any ordinary person with little trouble.

The food value of fungi is not very high if we judge merely by calories, but they serve as an attractive addition to meals or as flavouring and have, moreover, a vitamin content, B and D, and sometimes A, which is appreciable. To purchase cultivated mushrooms at their present exorbitant price is uneconomical for anyone having to consider either food values or his purse, but there is no reason why in rural districts there should not be some organized scheme by which information could be given about edible fungi and various methods of cooking them; they might even be sold in local markets. A little confidence but not rash experiment is all that is needed.

It is strange that in Europe and North America only the field mushroom is cultivated and this by a method which apparently originated in France in the seventeenth century. Attempts have been made to cultivate truffles and other fungi on a large scale but without success. The Chinese and Japanese have cultivated shiitake, an edible fungus, on logs, for more than two thousand years, and in all tropical countries a species of Volvaria may be said to be cultivated, for special beds are prepared for its growth though there is no inoculation.

Parasitic and Saprophytic Fungi

Before it was recognized towards the end of the seventies of last century that bacteria are the main cause of certain diseases, it was known with some certainty that fungi occurred in association with diseases such as ring-worm and were usually regarded as causing them. A century ago, about the time when many of these fungi were first recognized, it was more customary than not to regard what we know now as a parasitic organism not as the cause of a disease but as the result of it. The penetration of one organism by another, with the resulting disease, and the spread of the contagion was first clearly recognized by Bassi, who after long years of research on the muscardine of silk worms showed that it was due to a mould now usually known as *Botrytis Bassiana*. It is difficult to realize that this work was published only a year before Queen Victoria came to the throne. During the following forty years there was as much advance in our knowledge of the nature of disease as there has been in the last forty years in methods of locomotion. There were many false starts and one of these was a tendency to regard all contagious human diseases as due to fungi. However, the true path was shown by a host of investigators whose names are prominent in the history of bacteriology, and the fungi were

* Substance of a Chadwick Public Lecture, entitled "The Interrelation of Man and Fungus in Health and Disease", delivered at the Chelsea Physic Garden on June 19.

gradually relegated to a minor position, though in Great Britain the pendulum has swung too far.

The commonest fungi which affect man are the members of the ring-worm group, some attacking the heads of children, others causing eczema-like eruptions on the skin; a frequent focus for the last type is between the fingers or toes, the usual pathogen then being *Epidermophyton interdigitale*. Infection of the feet by this or allied forms has become more common during the last few years, apparently being picked up on the recently popular sea cruises or in public or school baths, where bare feet encounter contaminated woodwork. The throat trouble 'thrush' is still occasionally troublesome in babies owing to the use of dirty feeding-bottles, but even women of the poorest classes have learned sufficient about hygiene to reduce materially the prevalence of this disease.

An important point about the majority of these mycological diseases is that they are due to fungi which can live either normally or secondarily as saprophytes. Thus *Oidium albicans*, the fungus of 'thrush', occurs in sour milk, and ring-worm fungi affecting cattle have been found growing also on the dung in the byre. The phenomenon is not surprising, having regard to its known frequency with disease-producing bacteria, but it is often overlooked. Not only man but also his ox and his ass are subject to occasional fungal infections, and birds and fish have also a few mycological diseases. Insects are very frequently attacked, one large family (Laboulbeniales) being confined to them as hosts and numerous genera are peculiar to certain insects. Attempts have been made to control insect pests by infecting them with their special fungus parasite.

The most important and numerous diseases caused by fungi are, however, those of plants. Though there are bacterial diseases of plants and also virus diseases, they are few compared with those due to fungi.

Although diseases of crops have been recognized since the earliest times—indeed it would be well-nigh impossible for them to have been overlooked—the urban population of to-day has little idea of the loss that occurs even when every civilized country has its phytopathological service. Estimates of the losses due to fungal disease have been published from time to time. Many of the older estimates refer to years when the losses were exceptional, but modern figures show what enormous losses occur every year. Thus it has been calculated that in the United States more than £10,000,000 is lost in an average year by stem-rust of wheat, whereas it may be five or six times that amount in a bad year; bunt takes an average toll of £2,500,000 and loose smut nearly £1,000,000—and these are not the only diseases which affect wheat, nor is the United States exceptional in the severity of these diseases. The losses in the main crops of the United States are estimated as ranging from two to fifty per cent; 200,000,000 bushels of maize, for example, are lost annually. The figures for world losses are astounding. The downy mildew of the vine has been estimated as causing an annual loss of £500,000,000. The classical example of what a fungus disease can do at its worst was shown a century ago by the potato disease. This disease spread all over Europe causing devastation and dismay. It afflicted Ireland, causing a famine which wrecked a British Cabinet and produced other political and economic effects the results of which are still apparent.

Disease also takes its toll of forest trees. Of the disease-producing organisms fungi are usually the more prominent. The large bracket fungi growing on the boles or roots of trees are for the most part wound parasites requiring some break or crack before they can gain entrance. The result of such an attack is generally a rotting of the heart wood. As the defect occurs in unworked wood it is known as 'wet rot', as opposed to 'dry rot' of worked wood. It should be obvious that the tree trunks which have been so attacked are in a state in which further decay can occur in certain conditions, but sometimes it is the practice merely to remove the parts which are visibly affected. But the filaments of a rot-producing fungus do not stop dead in their progress at the point where their destructive action is apparent, but have usually extended beyond this. Different fungi behave somewhat differently, and it is only a broad general outline that can be mentioned here, and that mainly to stress that care must be taken to ensure that timber affected by wet rot is entirely rid of mycelium before use for structural purposes, or alternatively that it is stored and afterwards used in conditions which do not permit the fungus to renew its growth.

A certain amount of decay takes place in timber yards and there are well-proved practices to reduce this to a minimum. What I have said about the possible continued presence of the mycelium of wet-rot fungi is important, for it is wood stored for use that is affected. Proper sanitation and aeration are the best preventives.

But, from the aspect we are considering, rot in worked wood, that is dry rot, is much more important. There are several kinds of dry rot, but by far the most destructive, the most widespread and the most abundant is that due to *Merulius lacrymans*. Strange to say, this fungus is confined to buildings. An outdoor form has been described, but it is very rare and of no consequence except

taxonomically. It would be difficult to overstress the amount of damage caused in buildings and the ease with which this could be prevented. Wherever there is imperfectly seasoned or damp wood with insufficient ventilation the fungus is almost certain to appear, sooner or later. Having got a start it is able to spread, passing by strands over or through substances from which it cannot obtain nutriment and devouring other woodwork with which it meets. Attacked wood is reduced to powder. Water is formed from the breaking down of the substance of the wood, and this enables the fungus to continue its growth. Excess water is exuded from the fungus as drops, which explains the scientific name of the fungus but puzzles many whose sole knowledge is that their house is said to be suffering from dry rot.

When the strands of Merulius cannot proceed farther they form fruit bodies with an olive-orange coloured honeycomb-like surface. These fruit bodies produce millions of millions of microscopic orange-coloured spores. A fruit-body a foot across, no unusual size, produces more than enough spores to infect every building in the British Isles. Frequently they form a layer on furniture and other objects in a house and often cause alarm where no other effect of the fungus had been noticed. I once had an egg sent to me which was almost wholly orange-coloured, and was able to assure the sender that there was nothing wrong with it but that the cellar where it had been kept was badly in need of attention.

It is well to stress the subject of dry rot at the present time. After the War of 1914–18, when there was a renewal of building, the prevalence of dry rot in some of the building estates was astounding. With proper ventilation and sound seasoned timber there need be no fear after this War of a repetition of the losses of the last building boom, but if precautions are not taken the damage resulting from dry rot will doubtless be even greater.

Not only food plants but also all food may be subject to fungal attack. Mouldiness is one of the commonest phenomena of everyday life, but it is not universally recognized that moulds are living organisms. Moreover, in common with other organisms, they have certain requisites for growth: they need certain food substances, a certain range of temperature and a certain amount of moisture.

The fact that moulds grow only between certain temperatures is acted on in our methods of preservation; preservation, broadly speaking, is the prevention of the deterioration brought about by fungi or bacteria. If food is kept below a given temperature moulds which can grow only at temperatures above this remain dormant. This is the basis of cold storage. There are many problems of cold storage, particularly with fruit, but these do not alter the general principles.

Not all fungi are incapable of growth at the low temperature at which chilled meat is transported and occasionally there is trouble from these, as, for example, in black spot (Cladosporium), white spot (Sporotrichum) and whiskers (Mucor and Thamnidium). It is noteworthy that *Merulius lacrymans* often occurs in cold storage plant and in refrigerator cars.

Freezing does not ensure the killing of the fungi but only that they are unable to grow, and in growing cause damage. Indeed the spores of many common moulds when dried can be taken down to the temperature of liquid hydrogen without loss of vitality, and are able to withstand the rarefied air, intense cold and blazing sunlight of the stratosphere.

When cold-store meat, fruit and other food is released for use, it is not, therefore, in a sterilized condition; so far as moulds are concerned, it is more or less in the same state as when it went into storage. The only practical method of sterilizing food is by heat, and to keep it sterilized all organisms must be kept out of contact with it or, as we say, no air should be allowed to get to it.

The spread of knowledge about infectious diseases in recent years has opened the eyes of the general public to the widespread occurrence of germs invisible to the naked eye. Invisible fungus spores, of all kinds, are also present in the air in prodigious numbers and have been shown to occur at a height of several miles. Moulds appear with such consistency on foodstuffs and other organic substances that formerly it was commonly thought that putrescence was universal and inevitable and that moulds are the consequence of the decay. It was partly because of this that the similar view about plant diseases was prevalent.

It may be truthfully said that it would be exceptional for any organic material which was not thoroughly dry to escape decay and destruction. Heat is the only safe sterilizer. The temperature needed is higher than is theoretically sufficient because many spores have highly resistant walls which the heat must penetrate to be effective. Sterilization is the basis of the procedure in fruit-bottling, and similar methods of fruit preservation. But obviously so soon as sterilized material is exposed to the air, so soon is it liable to reinfection. Some foods are more readily attacked by mould than are others; moisture has a good deal to do with this, especially if the food is enclosed. Thus biscuits if kept in a dry place, either in a tin or on a plate, will remain wholesome, whereas bread, especially when cut, will soon become mouldy in a bread pan, though not so quickly if left free to

the air, but fortunately the time taken is too long for it to affect ordinary household procedure in normal times.

This necessity for moisture was early discovered in man's efforts to preserve his foods, and 'sun-drying' is still practised with numerous fruits. Until 1924, when there was a Government Committee report on the subject, it had become the practice to add such substances as benzoic acid, boric acid and formaldehyde to various foods as preservatives. All these are harmful to some extent and their use was prohibited, except that it is permissible to add small quantities of antiseptics such as sulphurous acid to fruit juices or meat products.

Apart from some chemical solutions which are poisonous to fungi, there are many others in which ordinary moulds will not grow. For this reason fats and oils, vinegar and strong sugar solutions have their use in preserving food.

USE OF FUNGI

We should be more happy without parasites, at least those which affect us, our animals and the plants we use. But what if there were no saprophytes living on dead material? What if there were no decay and no decomposition?

In natural conditions, decay, paradoxical as it may sound, is a method of sanitation. As things are, we are dependent upon plants with chlorophyll for our existence and equally upon organisms without chlorophyll—the ones to build up organic structures, the others to remove them when life is ended. To take a single example. A forest floor as the trees grow is covered with leaves which are later turned into leaf-mould or soil. As the years pass and a tree's span of life is reached it dies and falls or breaks, or it may succumb to the attacks of parasites. Saprophytic fungi grow on the fallen log or broken stump and gradually, over the years, it is reduced to pulp and finally this is also added to the soil. This has gone on through the ages and to such effect that a primeval forest from this aspect looks very little different from a reasonably old plantation, though forestry sanitation demands that there the fallen trees and broken branches should be removed. But this natural removal of fallen trees, leaves, fruits, shrubs, herbs, as well as dead animals, is carried out by fungi and bacteria living saprophytically.

It is perhaps only in places where man congregates—villages, towns and cities—that there is real danger to himself from putrescent material. If he waits until it disappears by what we may call natural means, then there may result those epidemics which hygiene and sanitary science have taught us to expect.

In the centuries man has discovered that not all the effects of fungal activity result in making wholesome food and drink distasteful or poisonous. Every race has its fermented liquors. Most of these fermentations are brought about by yeasts which act on the sugar present in fruits, cereals, plant juices and such like with the production of alcohol. The infection of the yeasts was haphazard, and with experience some degree of certainty about the resulting products was attained. With increasing knowledge of the biological processes involved in the operations it has become possible to control some of the fermentations so that the same species is used under the same conditions with a more or less standard result. The best understood of these is the production of different kinds of beer, but similar scientific methods have been applied, though not so commonly, in the making of wine and cider. Also it is realized that there are diseases of beer and other beverages which are brought about by the growth of alien organisms.

The raising of dough by yeasts in bread-making and the ripening of rennet cheeses by Penicillium are now often controlled in the strictest manner. Many moulds have been found to be responsible for products which are desirable for various purposes. Sometimes this may be a new substance or it may be one profitable to produce by fermentation. As an example of the second is the production of citric acid by *Aspergillus niger*, a common and abundant mould. Until a few years ago, lemons were used for this purpose, but the fungus is so efficient that it is used even in Italy, formerly the chief source of the acid—and incidentally one which would not be available to us at present.

There are many other products which the study of fungus activity has made available in industry. When the biochemistry of fungi is more fully understood, we shall have the means of producing with ease many substances difficult to synthesize without their aid, and many as yet unknown substances which will have their uses. The achievements of the past give promise that the attempts to harness some of the activities of the organisms will be profitable.

Just as the fungus known as ergot, which causes a disease of rye and other cereals and which when eaten in bread brings about gangrene or convulsions, has so important a place in modern medicine that it is listed in the Medical Research Council's recent memorandum on drugs the production of which in the United Kingdom should be encouraged, so may we hope that eventually we may benefit by turning what at first sight appears unmitigated evil into something beneficial to mankind.

A RECORD OF THE CHANGING FACE OF BRITAIN

BY DR. VAUGHAN CORNISH

THE Committee for the Employment of Artists in War-time, supported by a grant from the Pilgrim Trust, has co-ordinated the work of landscape painters in recording (mostly in water-colour) the architectural gems of rural England with the background of their natural setting. The pictures now on view in the National Gallery, a selection of the first year's work, are arranged according to counties. Such pictures should be multiplied year by year until a complete collection has been made which can be housed for permanent exhibition.

The value of the collection now begun is both historical and educational. The former has, of course, to do with the possible loss of these objects of beauty. This loss may occur in one or other of two ways—destruction by the Huns in war-time, or replanning by Vandals in the succeeding years of peace.

The educational value of this new collection of pictures is especially important in relation to the period of replanning and reconditioning. Whether England's beauty will then be restored or obliterated will depend not only on the accident of individual talent in architecture and administration, but also on the wider diffusion of artistic culture which will ensure that public opinion will not mistake the aberrations of bad taste for the originality of genius.

As we look through the present collection in the National Gallery we find that the subjects recorded as of local or period interest include indoor as well as outdoor scenes of rural architecture—timbered roofs and the paraphernalia of the mills which grind the corn we grow.

The exterior of a windmill is shown in the picture of Dolce Mill, Rochester, by Thomas Hennell. Looking upon this, it is easy to realize the imaginative impression of a four-armed giant which led Don Quixote to emulate the achievement of legendary knights.

The villages and small country towns of Buckinghamshire are charmingly illustrated by Stanley Anderson, R.A.; in Beaconsfield the architectural features surrounding a *place* (for which we have no English name altogether equivalent); in Amersham an interesting Market Hall; and in Long Crendon an old house with the outside chimney shaft which was a picturesque addition to rural architecture at an early date.

The view of Chesham, Bucks, by W. P. Robins, is a landscape proper in which the church spire and neighbouring cottages are minor, decorative features nestling in a well-timbered valley below tree-capped hills.

The street of Hadleigh, by A. Newton, shows the timbered houses with overhanging upper story, which are characteristic of a Suffolk village.

An excellent example of architecture with natural background is seen in Charles Knight's picture of a Sussex farmstead at the foot of the bold slopes of the open chalk downs. Birdham Mill, by W. Russell Flint, R.A., shows a picturesque building set amidst the winding waters of Chichester Channel, a remote corner of Sussex.

Among the line drawings, of which there are a few among the many water-colours, that by S. R. Badmin of a bridge over the Ouse at Chellington, in Bedfordshire, records one of the numerous survivals of medieval arches, the beauty of which is often enhanced by reflexion in the placid streams of the English lowland.

Of buildings in the north of England, the picture of Livesay Hall, in Lancashire, by W. Fairclough, shows an unusually complete preservation of stone-mullioned windows, which are too often replaced by modern woodwork out of harmony with stone fabric.

The market-place of Thame, in Oxfordshire, by Stanley Anderson, R.A., is depicted, as is proper, on market day; for without the gathering of countrymen the picture of a market-place is one of form without function.

From Gloucestershire we have the double dovecote of Coln St. Aldwyn, by George Bissell, an example of the Cotswold style which is a blessed survival of one of the best types of English rural architecture.

A number of interesting examples of the architecture of south-western England are shown in the distinctive water-colours of S. S. Longley: in Dorsetshire the village of Corfe, and the Saxon church of Wareham, which stands in a remarkable position above the sunken road which enters that ancient town. In Devon we have Brixham, with its houses on a steep slope above the little harbour where lies the fishing fleet amidst the reflexions of lapping waves which come gently in from the broad waters of Tor Bay.

Lastly, we come to Longley's simple but charming water-colour of the old farmhouse of Thorn in Salcombe Regis, near Sidmouth, which takes its name from the historic Thorn Tree, close at hand, renewed again and again since Saxon times, and it may even be from yet earlier days.

DIRECT PETROL INJECTION *versus* THE CARBURETTOR FOR THE INTERNAL COMBUSTION ENGINE

REPLYING to the debate upon aircraft supply in the House of Commons, on July 10, the Minister of Aircraft Production, Lieut.-Colonel Moore-Brabazon, mentioned that where the British aero engine industry uses the carburettor, the Germans have adopted the fuel injection system. The use of direct fuel injection, as an alternative to the carburettor of spark-ignition aero-engines, is put forward in some quarters as a cure for the many shortcomings of the carburettor engine, and, in particular, as a means of improved performance at altitude. The injection may be made either before the entry to the supercharger, into the induction manifold, or directly into the engine cylinders. The German systems inject direct into the cylinders, which, having regard to the all-round advantages of the three methods, is probably the best position.

The claims to superiority of the injection system as compared with the carburettor are as follows:

(1) No restriction is offered to the free 'breathing' of the engine, because the pressure drop necessarily incurred at the venturi of the carburettor (and not recovered) is eliminated. This pressure drop is about 1 in. of mercury at ground-level and increases with altitude if the air-flow is constant, because of the fall in air density. It is only significant at altitudes above the 'rated' or full-throttle height. If the venturi is made larger, so as to reduce the 'throttling' at high altitudes, the pressure drop available for fuel metering may be inconveniently small at lower altitudes. Further, eliminating the carburettor gives a clearer entry for the air into the supercharger. The total effect, above the rated altitude, is to increase the height at which a given boost pressure, and therefore power output, is available, and hence to improve the ceiling of the aircraft. It should be noted, however, that the beneficial effect of fuel cooling, in increasing the pressure ratio of the supercharger, is lost, a factor tending to outweigh the gain conferred by reduced restriction to the air-flow. The disadvantage of a low metering pressure can be eliminated by using a 'blown' or pressure carburettor after the supercharger.

(2) The induction system is freed from the hazard of 'refrigeration' icing, because the effect of evaporative fuel cooling is absent. This is a very real advantage as compared with the now obsolescent unheated carburettor, but carburettors are available which are immune from freezing trouble.

(3) There is superior fuel economy due to perfect distribution to individual cylinders. It should be noted that the air distribution is, however, unaffected. Comparative tests indicate that there is little difference in economy between the carburettor and the injection system, at least at normal air temperature. It is possible, however, that at high altitudes, when it is known that distribution becomes poor, the injection system may score. Alternatively, fuel of lower volatility may be used, although it is understood that fuel taken from German tanks indicates that no reduction in knock-rating is being made.

(4) Freedom from inertia effects. This is a definite advantage during fighting manœuvring, but it applies only to the float-type carburettor. Pressure-injection carburettors are available which are equally unaffected by altitude or acceleration.

(5) Reduced risk of vapour-lock at high altitudes, due to the absence of fuel pressure drops in the system and the accompanying risk of vapour evolution. The injection pumps themselves are susceptible to vapour and air in the fuel supply and the Germans fit de-aerators to deal with this risk.

(6) The injection system would be essential for a two-stroke cycle engine in order to eliminate fuel waste during the scavenge period, unavoidable with a carburettor.

It appears that, on balance, the injection system, as compared with many present carburettors, has some slight but definite advantages. Against these must be set the extra complication of the fuel pump and nozzle, and the high standard of accuracy essential to their production and maintenance. This latter question is not without its importance under war conditions. The Junkers system comprises 1,576 parts, 327 being different, and weighs 60 lb., as compared with the Rolls Royce Merlin's 433 parts, 141 being different, and weighing 25 lb. There is also likely to be a definite speed limitation to the injection pump, whereas no such limitation applies to the carburettor.

OBITUARIES

Sir Arthur Evans, F.R.S.

ARTHUR JOHN EVANS was born on July 8, 1851, at Nash Mills, Hemel Hempstead, Herts. The son of John Evans (afterwards Sir John Evans, K.C.B.), the most eminent prehistoric archæologist of his day, he was educated at Harrow and Brasenose College, Oxford, where he took first-class honours in history. It was not, however, formal education that played the most important part in the development of his mind. From his earliest years his surroundings were a training for his future career. In 1859 John Evans was appointed one of a committee of three which crossed to France to pronounce on the origin of the worked flints which Boucher de Perthes had discovered in the valley of the Somme and had claimed to be the earliest known tools and weapons of man; and his home and the great collections of antiquities of the stone, bronze, iron and later ages, which he was then forming, were the centre of the discussions on early man and the earliest evidences of human handiwork in which Sir John Lubbock (afterwards Lord Avebury), Sir Charles Lyell, Boyd Dawkins and others were taking part with him in the earlier years of the latter half of the nineteenth century.

If this atmosphere of archæological discussion played its part in determining the bent of Arthur Evans's intellectual development, no less important was his familiarity with his father's vast collections. There he derived that flair in handling antiquities which gave him an almost uncanny judgment in analysing the formative influences which pointed to their cultural derivation and constituted his great strength in the constructive interpretation of the evidence which he won from archæological sites with the spade of the excavator.

As an archæologist, Arthur Evans was interested in the development of form rather than in the study of the technical processes of production in which his father had excelled. His attention mainly turned in the direction of the bronze and iron ages, the latter then little known in Britain, rather than to the stone age. It was this interest in form which, when he had been for some years a fellow of Brasenose College, Oxford, especially fitted him for his appointment as keeper of the Ashmolean Museum. This post he held from 1884 until 1908, when he became honorary keeper.

Evans's fame as the excavator of Knossos and the discoverer in Crete of the bronze age civilization of the Mediterranean has tended to obscure the eminence of his achievement in British archæology, but his account of his excavation of the iron age burial site at Aylesford in Kent will always be a classic of reference and of crucial importance for the study of the British iron age, while his research on the origins of Celtic art in Britain, which were summed up in his Rhind Lectures of 1895, unfortunately never published, had a fundamental and abiding effect on the future development of that branch of archæological investigation. This department of Evans's research, however, proved to be of even greater and more far-reaching significance, for it was this which first turned his attention in the direction of the Mediterranean and the investigation of the relation of the forms of the prehistoric culture of the Europe of north and west to that of the south and east, a subject to grow under the hands of Oskar Montelius, the Swedish archæologist, and George Coffey, of Dublin.

In carrying out his duties as keeper of the Ashmolean, Evans showed all that vigour, determination of character and capacity for organization which were afterwards to stand him in good stead as an archæological excavator. He organized that venerable institution and made it an integral part of the University. He also undertook archæological exploration in 1873–74 in Finland and Russia, and in the following years he paid the first of a series of visits to the Balkan peninsula.

Evans's early travels of the Balkans were of no little consequence in more directions than one. His experiences were embodied in a series of letters from Illyria to the *Manchester Guardian*, which afterwards appeared in book form, and were thought by some to contain much of his best work as an observer and man of letters. Here he showed acute powers of seizing the essentials of a situation at a time when tension between Italian and Slav under Austrian rule was rapidly attaining breaking point. Like most Westerns who visit the Balkans, Evans became a partisan. Convinced of the justice of the claims of the Slavs, who, though numerically vastly in the majority, had little voice in affairs, he actively espoused their cause, and in 1882 was thrown into prison by the Austrian authorities for his participation in the Crivoscian insurrection. He never lost his sympathy with the Slav, and during the War of 1914–18 he was one of the most active supporters of the movement which led to the formation of the kingdom of Yugoslavia.

In the early 'nineties, Evans began his archæological exploration of Crete. In part he was attracted by the possibility of finding evidence bearing on the origin of the alphabet and early forms of writing, and in 1893 his search was rewarded by the discovery of a pre-Phœnician script. But as time went on, the importance of the island in an archæological sense became increasingly apparent. The excavations of Schliemann at Troy, Mycenæ and Tiryns, which began in 1866 and had been continued on more scientific lines by Dorpfeld, as well as the work of other excavators which was being carried on at other sites in the eastern Mediterranean area, pointed to the existence of a previously unsuspected civilization which was not the Greece of the Homeric age, much less the inheritance of classical times. Evans's personal knowledge of Greece and the eastern

Mediterranean, and the general archæological situation, pointed in the direction of Crete as a strategical strong point; while Petrie's discoveries in Egypt in the later 'nineties demonstrated the existence as a menace to that kingdom in the eighteenth and nineteenth dynasties of some strong maritime confederacy to the north. As was soon to be shown, Evans's confidence and perseverance were justified. In 1900, at Knossos, he discovered the first traces of the Palace and the earliest evidence upon which he was to rear the structure of Minoan civilization, and, in conjunction with material brought by other archæologists, British, American, Greek, French, German, not only from Crete, but also from the mainland and Asia Minor, to reconstruct the whole of the forgotten bronze age culture of the Mediterranean.

From 1900 until 1908, Evans was engaged in the excavation of this site at Knossos, and year by year at meetings of the British Association, the Society of Antiquarians in London and elsewhere, as well as in the publications of the British School at Athens or the Hellenic Society, he reported on his discoveries. So far as was possible, preservation and reconstruction followed exploration, and in 1925 the site, which he had purchased, and the Palace, were handed over on a trust to the British School of Archæology at Athens as a museum and for purposes of archæological research.

At the close of his excavations, Evans had completed the tale of the whole bronze age, so far as revealed on the site at Knossos, covering a period of two thousand years or more and extending from neolithic times down to the final destruction of the Palace at the dawn of the iron age. It is true the one site did not always tell the story in full, but what was lacking was found on other sites of the island, Palækastro, Gournia, Messara, and so forth. Evans's achievement did not rest there, and it is largely due to his genius in interpretation and cultural analysis that we now know the relations of Crete with Egypt and North Africa, with the mainland and islands of Greece, with their Helladic culture, and Asia Minor, and can accept as well founded his reasoned conclusions as to the origins and the influences which built up this great prehistoric civilization.

The work of final analysis and exposition of the evidence from Knossos was long and arduous, and will in itself explain the fact that from 1900 onward, apart from contributions to the periodicals of learned societies, Evans's writings, though all important, were not great in bulk. Of these the most important or considerable are his "Tree and Pillar Cult" (1901) and his "Scripta Minoa" (1909). His account of the excavations as a whole was given to the world in four large volumes under the title "The Palace of Minos", of which the first appeared in 1922 and the fourth in 1935. The completion of the last volume was celebrated at the close of 1934 by Evans's friends and admirers, who presented to him a portrait bust (see NATURE, Dec. 22, 1934, p. 962).

Enough has already been said to make it unnecessary to attempt any further estimate of the value of Arthur Evans's contribution to archæological research. He added a whole chapter, and that one of the most important and crucial, to the history of civilization. From the year 1900 his work became fundamental in determining the course of all future research, not only in the Mediterranean area, but also in the whole region which has been the arena of development of modern civilization. It is perhaps not the least striking evidence of his force of character and strength of intellect that when he made his first discovery at Knossos, he had attained his fiftieth year, and at a time when most who have not already reached the highest attainment can scarcely hope to achieve eminence in a new field, he added to a reputation already established by an achievement second to none in modern archæological investigation.

Arthur Evans naturally and deservedly was the recipient of many honours. In 1911 he was knighted. He was a D.Litt. of Oxford, hon. LL.D. of Edinburgh and Dublin, and hon. Ph.D. of Berlin, a fellow of Brasenose College, Oxford, and fellow of the Society of Antiquaries of London, of which he was president 1914–19. In 1916 he was president of the British Association for the Advancement of Science, an office which he accepted with extreme reluctance, owing to what he felt to be the claim of national duty during the War. So long ago as 1901 he was elected to the Royal Society, which gave him its premier award, the Copley Medal, in 1936. He was awarded the Royal Gold Medal of the Institute of British Architects, the Petrie Medal for archæology, and was Frazer Lecturer in 1930. The more important Continental societies and academies which include archæology within their scope had recognized his work by honorary membership.

By the death of Sir Arthur Evans on July 11, only three days after celebrating his ninetieth birthday, following so closely on the death of Sir James Frazer, archæological and anthropological studies have lost two outstanding figures of international stature.

BOTH in the range of his learning and accomplishments, and in his positive contributions to knowledge, Sir Arthur Evans was an outstanding figure among nearly three generations of archæologists. He owed much to intimacy with his distinguished father, Sir John Evans, whom in some respects he closely resembled; much to the historian Edward Freeman, who encouraged him at Oxford; much to a year's study at Göttingen, to which he would refer with affection and gratitude.

But Evans's peculiar gifts were his own. His eyesight, though not seriously hampering him in field work, gave him a microscopic insight into the finest craftsmanship of gems and coins, enabling him to detect many minute signatures of ancient artists, and so to demonstrate the attribution of similar designs to the same hand. His remarkable flair for objects that interested him had already brought him treasures in other fields of exploration—Illyria and Sicily in particular—before he embarked in middle life on the Cretan adventures which made him known to a wider public.

His strong devotion to freedom and political

justice brought him into close relations with men of many nationalities and creeds, and gave him access to regions and communities which had been visited by few. His interest in the Southern Slavs and in the Cretans began while they were still dominated by the Turks, and he had the satisfaction of witnessing their liberation; it was indeed appropriate that the Yugoslav State and its Academy should be represented at his memorial service in Oxford. His genius for friendship, and for attracting devoted help from all classes made easy the conduct of archæological excavation on a very large scale, with the large private means which were as generously lavished on the Boy Scout Movement and other social services, as on his expeditions and collections.

Evans's beautiful home at Youlbury became a place of pilgrimage for colleagues from many lands, and a centre of wise counsel and unstinted help, especially to the younger workers. Few men so thoroughly enjoyed a full and strenuous life, or did more to enable others to do the same.

J. L. MYRES.

NEWS AND VIEWS

Reconstruction in Great Britain

IN a statement made in the House of Lords on July 17, Lord Reith, Minister of Works and Buildings, announced the publication of an interim report of the Uthwatt Committee, and stated that the Government is to take immediate steps to implement many of the recommendations. The Government is, of course, already committed to the principle of planning in redeveloping the country, but it is reassuring to learn that the Committee's recommendation that any action taken now to secure the orderly planning of areas which include substantially devastated sites must be planned as a whole, is to be accepted; and also that the further recommendation to have such areas defined is to be implemented as soon as the necessary legislation can be effected. The Committee has also recommended the setting up of a central authority to control building development by licence. On this point Lord Reith was not inclined to go so far; the Government view is that emergency powers over building are already stringent, and they have been reinforced by the control of payments made under the War Damage Act; further safeguards can be given by strengthening the Planning Acts.

The urgency of the problems of reconstruction appears to be now fully appreciated. Lord Reith stated that the Government agrees that all necessary preliminary steps for a national plan should be taken as soon as possible in order to ensure that local development shall be in harmony with national requirements. While Mr. Greenwood, Minister without Portfolio, is still to undertake the general study of post-war problems, Lord Reith is to have special responsibility for long-term planning policy in town and country in the sphere of physical reconstruction. To co-ordinate this work of forward planning with current administration, a Council of Ministers, consisting of the Secretary of State for Scotland, the Minister of Health, and Lord Reith (chairman), has been appointed. This Council of Ministers may prove to be the beginnings of the Central Planning Authority urged by the Uthwatt Committee, and indeed Lord Reith himself said he regarded it as having been established in embryo.

Russian Foreign Policy

THREE further Oxford Pamphlets on World Affairs are of particular interest in view of recent events. Miss Barbara Ward's "Russian Foreign Policy" (No. 34), while not dealing with events beyond the Finnish war, is of interest as an attempt to interpret Russian foreign policy free from ideological preconceptions, on the assumption that neither her problems nor her approach to them are in the last analysis very different from those of her neighbours. Miss Ward traces the foreign policy of the U.S.S.R. from the first year of its existence and its preoccupation with keeping its lands intact and its frontiers inviolate, through the failure of world revolution and the period of concentration upon economic contacts and peaceful diplomatic relations with the outside world, to Russia's entry into the European system of collective security. Obstacles to closer co-operation with the West and the influence of the Anti-Comintern Front are discussed as well as the events leading to the isolation of Russia, the Non-Aggression Pact with Germany and the Finnish war, and the underlying principle in Russian policy—security—is stressed.

Italian Foreign Policy

IN a further pamphlet (No. 48) Miss Ward attempts to place in their proper perspective the answers to such questions regarding Italian foreign policy as why Italy waited nine months before declaring war, and why she entered the war against old allies on the side of a hereditary enemy. Miss Ward indicates the consistency of Italy's policy, and states that the failures of her arms and diplomacy to-day were already predictable when she started her career as a great power some seventy years ago. Her reduction to colonial status as a dependency of the German Reich was always inherent in her policy of seeking aggrandizement without the military strength to secure it single-handed. Italy's humiliation will only be banished in a society in which great powers are no longer measured in colonial empire and military strength; in a fully organized European society of nations, Italy could play a leading part.

Holland and the War

This aspect is obviously of interest in relation to the question of European order on which Prof. G. N. Clark's pamphlet (No. 49, "Holland and the War") has an important bearing. Prof. Clark gives a picture of the economic position of Holland, her social structure and her constitution, and against this background describes her foreign policy in recent years and the circumstances under which she entered the War with her powerful material resources in the East Indies. He describes briefly the effects of the German occupation and Holland's aims in the War—a just and stable international order—and emphasizes the value of the freedom of the Netherlands to the civilization of the world. The preservation of that freedom, when restored, depends on the collective strength and wisdom of the friends of justice.

Carnegie United Kingdom Trust

The twenty-seventh annual report of the Carnegie United Kingdom Trust (Dunfermline: The Trust) covers the year 1940 and emphasizes the aim of its war-time policy to continue so far as possible to foster pioneer experimental work which may be expected to have an enduring effect on the social structure of the country. It also aims at safeguarding its own past work where this has proved to be of value by assisting earlier beneficiaries to maintain their services and, if necessary, extend them to meet special needs arising from the War. The year 1940 was the last year of a quinquennium, and the report briefly reviews the allocations made during that period. The largest single allocation was one of a £150,000 for land settlement schemes to be undertaken in England and Wales by the Land Settlement Association. The policy of this Association had to be completely re-orientated at the outbreak of war. At September 30, 1940, there were 1,054 holders on full-time estates, and the land has been brought under cultivation for production of corn, potatoes and other crops under schemes agreed with the county war agricultural committees. Individual grants to the National Council of Social Service have been rounded into a single block grant of £5,000 for 1940 to cover all those of the Council's activities in which the Trust is interested.

In the field of adult education, the main allocations during the period have been for the adaptation and equipment of Lord Lothian's gift of New Battle Abbey as a residential college for adult education and for two special inquiries into the problems of young people between the ages of eighteen and twenty-five. The preliminary area reports in the Age Group Enquiry reached an advanced stage of completion by the autumn of 1939, and the report covering the Cardiff district is being published independently under the auspices of the South Wales Council of Social Service and the Welsh University Press Board. The continued development of the Regional Library Bureaux presents the most interesting feature of library history of the last five years, and reference is made in the report to the assistance given to these Bureaux as well as to the National Central Library. Bulk allocations approved for 1941 include £8,000 to central libraries, £5,000 to the National Council of Social Service, £20,000 for youth services and £3,500 for land settlements. An immediate grant of £2,700 has been promised to the National Council of Girls Clubs to establish a bursary fund for training potential youth leaders and the salaries and expenses of supervisors of training. A grant of £2,000 for experiments in Oxfordshire on the establishment of a number of youth service camps has also been promised.

Acoustics of Argentine Chamber of Deputies

A description is given by S. D. Wilburn and S. C. Tenac in *Electrical Communication* (19, No. 3; 1941) of the system of microphones and loud-speakers designed by the Union Telefonica for the Argentine Chamber of Deputies in Buenos Aires and installed late in 1939. Investigation showed that the pronounced acoustical difficulties of the Chamber were due solely to the absence of reverberation. Structural alterations were not feasible and a system including a microphone for each individual had to be devised. The new system was first used officially at the opening session in 1940, and has given great satisfaction. It comprises 193 microphones and four loud-speakers in the Chamber. It has two independent channels of transmission: one with five microphones consisting of one each for the president of the Chamber of Deputies and the two secretaries and two on the ministers' table; the other channel is equipped for 188 individual-microphones for the deputies. The Chamber is completely surrounded by two walls with three-metre corridors between them at various heights. The four loud-speakers are located in the first gallery. A simple schematic circuit diagram of the transmission, switching and power circuits is given. The electric power consumption of the system is only 1·1 kilowatts.

Sylviculture of some Tropical Trees

To the forester versed in tropical forestry and who has had the opportunity of discussing sylvicultural problems with the mixed gathering found at an international forestry congress, perhaps the most interesting section in the *Malayan Forester* (January, 1941) is that in which observations are made on the sylvicultural characteristics of some of the important timber species. The coppicing powers of dipterocarp regeneration show that *Dryobalanops oblongifolia*, *Dipterocarpus Kerrii* and the balan and the white *meranti* groups of *Shorea* coppice fairly freely, while the red *merantis* and *merawan* (Hopea spp.) do not. There appears also to be some indication that ability to coppice and hardiness go together; for example, *Shorea ovalis* is one of the few red *merantis* to show some ability to coppice, whilst it has also shown itself more tolerant of transplanting than most of its group. How valuable are such practical notes is known only to those tropical foresters scattered about in India, Africa and elsewhere, who are dealing with similar problems with

valuable timber trees of the same genera or families, the knowledge of the secrets of the regeneration of which is absolutely vital to the work of replacing the often primeval stands he is dealing with.

It was the Indian forest officer (should we now say the Burman forest officer ?) who first studied the effects of firing the forest floor in the interests of obtaining successful regeneration of a valuable timber species. In Malaya preliminary investigations show that burning of the undergrowth is a prerequisite for the regeneration of *Melaleuca leucadendron*. An intentionally burnt area and one accidentally fired were equally successful in a covering of germinating seedlings; whilst an adjoining unburnt area appears to be as devoid of regeneration as ever. These practical observations in the forest (they cannot be undertaken in a research laboratory) are of the very greatest importance and of absorbing interest. In the case of the tropical forest they had their first beginnings in India, where a considerable amount of information had been collected by the end of last century. The present century has witnessed in some cases the results being put to a practical use.

Antarctic and Sub-Antarctic Starfishes

THE Asteroidea of the Sub-Antarctic and the Antarctic and a few from South Africa collected by the *Discovery*, *Discovery II* and the *William Scoresby* have been described by W. K. Fisher (Discovery Repts., 20; 1940). Seventeen new species and three new forms of previously described species are described. The author gives a critical list of all the valid species from the antarctic and sub-antarctic, which number 114. He himself deals with 113 different forms, not all separate species and not all from the main region, and from the number and wide range of specimens in some of them he is able to add considerably to our knowledge of these animals. The additional information thus gained has enabled him to revise certain groups. Thus the memoir is not merely a record of species obtained but also a noteworthy contribution to our understanding of the asteroids in southern latitudes. Perhaps the most interesting species is *Odinella nutrix*, which is the only known member of the Brisingidæ to possess a marsupium, and this is entirely different from that in any other group of starfish possessing brood chambers. The work is illustrated by twelve photographic plates and eighteen plates of figures.

Earthquake in Japan

DURING the night of July 16–17 a strong earthquake shook the northern part of the Nagano Prefecture, some 140 miles north-west of Tokyo. It is not yet known whether there were any casualties or not, but more than thirty houses collapsed and the railway between Nagano and Niigata Prefectures was interrupted for a short while. Japan is well known at present to be in a seismically active zone for earthquakes of all focal depths. Tremors, minor shocks and even strong earthquakes as in the case cited above are moderately frequent and very large earthquakes are by no means uncommon as, for example, the Kwanto earthquake of September 1, 1923, which nearly destroyed Tokyo and Yokohama, causing tremendous loss of property and the deaths of 250,000 people, the Tango earthquake of March 7, 1927, and the Idu earthquake of November 26, 1930.

Earthquakes Registered in Switzerland during 1939

THE complete bulletin of the Swiss Seismological Stations at Zurich, Chur, Neuchâtel, Basle and Sion for 1939, compiled by Dr. E. Wanner, has just been received. It contains, besides details of equipment, three tables and six maps. The first table and the maps concern earthquakes with epicentres in Switzerland, twenty-one of which were felt by people during 1939. The greatest intensity reached was five on the Rossi-Forel scale, this being on seven occasions: at Brig-Visp on May 18; at Martigny on August 23; at Unter-Engadin on September 26; at Aargau on November 17; at Sion Lokalstoh on November 20; at Oberes Baselbiet on December 5 and at Innerferrera on December 7. The second table contains a list of the details of ninety-one near earthquakes, whilst Table III contains a list with details of 178 distant earthquakes registered by the Swiss observatories during the year.

Max Jaffé (1841–1911)

PROF. MAX JAFFÉ, an eminent German biochemist and pathologist, was born at Grünberg in Silesia on July 25, 1841. He received his medical education in Berlin, where he qualified in 1862. While still a student he took a keen interest in chemical investigations and worked in the Pathological Laboratory under the direction of W. Kühne. During 1865–1872 he was an assistant in the medical clinic at Königsberg under Leyden, with whom he published a work on putrid sputum which led to the discovery of the spirilla and leptothrix characteristic of putrid processes in the lungs. In 1872 he was appointed extraordinary professor and in 1880 full professor of pharmacology and medical chemistry in the Königsberg faculty. His principal work consisted in the discovery of urobilin and urobilinogen in the urine and their origin in the bile, his studies of indican and creatinin, with the tests with which his name is associated, and his investigations in urocaninic acid in the urine of dogs and of ornithin in the excrement of birds. Jaffé had an extensive consultant practice and enjoyed a high reputation as a teacher. He died on October 26, 1911.

Armauer Hansen (1841–1912)

DR. GERHARD HENDRIK ARMAUER HANSEN, the celebrated Norwegian leprologist, was born at Bergen on July 29, 1841. He received his medical education at Christiania and qualified in 1866. Two years later he was appointed assistant physician to the leprosy home at Bergen under the direction of Dr. D. C. Danielssen, the founder of the scientific study of leprosy. In 1874 he read a paper before the Medical Society of Christiania, which was published in a

special number of the *Norsk Magazin for Laegevidenskaben* on the etiology of leprosy in which he demolished the theory of heredity, brought forward evidence in favour of its being a specific infectious disease, and described rod-like bodies in the lesions, which he afterwards named *B. lepræ* and regarded as the cause of the disease. His results were confirmed by Prof. Neisser of Breslau, who went to Bergen to examine Hansen's material. Hansen's contention that leprosy was an infectious disease was generally accepted, and led to laws being passed enforcing isolation and disinfection as in the case of other infectious diseases, with the result that the number of lepers in Norway showed a considerable diminution. Hansen received many honours, including the doctorate of the University of Copenhagen and the erection of his statue in the gardens of the Bergen Museum eleven years before his death, which took place on February 13, 1912.

Plastics

WE have received a copy of one of the Pelican Books entitled "Plastics", written by V. E. Yarsley and E. G. Couzens (Harmondsworth: Penguin Books, Ltd. Pp. 160+24 plates. *6d.*). This gives a very interesting account of the chemistry and physics of modern plastics and the methods of manufacture and the application of plastics. It is well illustrated and provided with an index.

The Night Sky in August

FULL moon occurs on August 7 at 5h. 38m. U.T. and new moon on August 22 at 18h. 34m. The moon is in conjunction with Mars on August 12, with Saturn on August 15, with Jupiter on August 17, and with Venus on August 25. At the beginning of the month Jupiter and Saturn are morning stars, their times of rising being soon after midnight and 23½h. respectively; at the end of August the times are approximately 22½h. and 21½h. The planets are easily recognized in the constellation of Taurus. Mercury rises at 3h. at the beginning and at 6h. 15m. at the end of the month and is in superior conjunction on August 19. Venus rises at 9h. and 7½h. approximately at the beginning and end of August and is in conjunction with Neptune on August 18. Mars is in the constellation of Pisces and rises shortly after 22h. at the beginning and at 20½ h. at the end of the month. The Perseid meteors reach their maximum on August 10–12, their radiant point being close to η Persei. The bright star α Tauri will be occulted by the moon on August 16d. 13h. 12m. approximately.

Announcements

THE George Cross has been awarded posthumously to the Earl of Suffolk, chief field research and experimental officer, Directorate of Scientific Research, Ministry of Supply, "for conspicuous bravery in connexion with bomb disposal". Lord Suffolk was the leader of a 'team' of three, the other two being Miss E. B. Morden (secretary) and Mr. F. W. Hards (mechanic), both of whom are commended for their work during the six months before they were killed.

LORD HAILEY has been appointed president of the Royal Central Asian Society, in succession to the late Lord Lloyd. The Lawrence of Arabia Memorial Medal has been awarded to Captain C. E. Corry, Iraq Police, author of "The Blood Feud", for his successful work in the tribal country of Iraq, and his study of the Marsh Arabs.

MR. J. P. R. RICHES, of Clare College, Cambridge, has been appointed to the Frank Smart studentship for research in botany for one year from October 1.

MISS D. F. BLEEK of Cape Town has been awarded the South African Medal and grant for the year 1940–41 by the South Africa Association for the Advancement of Science for her researches on the Bushmen, and is at present busy on her Bushman dictionary.

THE Jones-Bateman Cup for research in fruit-growing is offered triennially by the Royal Horticultural Society for original research in fruit culture which has added to our knowledge of cultivation, genetics, or other relative matters. The work dealt with should have been mainly carried out by the candidate in the United Kingdom, and mostly during the past five years. Candidates should submit accounts of their work by October 31.

THE following officers for 1941–42 of the Institution of Electrical Engineers have recently been elected: *President*, Sir Noel Ashbridge; *Vice-President*, Prof. S. Parker Smith; *Hon. Treasurer*, Mr. E. Leete.

THE Council of the Royal Society of Arts offers under the Thomas Gray Memorial Trust a prize of £50 to any person who may bring to its notice an invention, publication, diagram, etc., which in the opinion of the judges is considered to be an advancement in the science or practice of navigation, proposed or invented by himself in the period January 1. 1936—December 31, 1941. Competitors must forward their proofs of claim, between October 1 and December 31, to the Secretary, Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2. In 1940 the Council offered a similar prize, which was awarded to Mr. H. C. Walker, of Cheam, Surrey, for a device known as the "portable valve lifeboat equipment", a self-contained radio auto-transmitter.

ON July 10, the honorary degree of LL.D. in the University of Aberdeen was conferred on the following: Dr. A. W. Falconer, principal and vice-chancellor of the University of Cape Town (*in absentia*); Prof. J. C. Philip, emeritus professor of physical chemistry in the Imperial College of Science and Technology, London, and president of the Chemical Society; Sir Alfred Zimmern, Montague Burton professor of international relations in the University of Oxford.

The ordinary degree of D.Sc. was conferred on F. Landgrebe, for a thesis entitled "A Comparative Study of the Autocoids of the Pituitary Gland", and on Dr. T. S. Westoll, for a thesis entitled "The Haplolepidæ: a New Family of late Carboniferous Bony Fishes".

Diffuse Spots in X-Ray Crystal Photographs

THE pattern of 'diffuse spots' in X-ray crystal photographs which has been recently the subject of much observation and discussion can, so far as has been examined, be calculated from the first principles of wave interference. It is the true diffraction pattern of the crystal lattice considered as a three-dimensional grating. Neither thermal conditions nor elastic properties enter into the calculations. I have discussed the case of sylvine in NATURE, 146, 50 (1940): I gave the results for diamond and calcite in the course of a discussion at the Royal Society on February 6, 1941; Preston's summary of the discussion appeared in NATURE, 147, 467 (1941). A more complete account of these comparisons of theory and experiment together with additional examples are in course of publication by the Royal Society.

Up to the present, the agreement between this true diffraction pattern and the observed effects is within the errors of experiment. Every observation finds its correlation in the pattern, though spots are not always observed where correlation could have been found. The correlation extends to such details as those that have been described by Mrs. Lonsdale for diamond (see accompanying letter), where the diffuse spots in some cases show curious extensions and in others break up into groups of smaller spots. Mrs. Lonsdale has recently found that the less common form of diamond, that which is especially transparent to infra-red and ultra-violet, does not present these minor details. In both cases the geometry of the observed pattern shows correlation with the true diffraction pattern so far as it goes: in one case it goes farther than in the other.

It is, of course, true that the effect calculated in this way ought to be far too weak to be observed in a perfect crystal composed of a considerable number of scattering centres as must be the case when the usual Laue pattern is observed. Why, then, is the true diffraction pattern observable after all? A satisfactory theory must answer this general question. It must account, among other things, for the diamond peculiarities.

Diffuse X-Ray Diffraction from the Two Types of Diamond

SIR Robert Robertson, Dr. J. J. Fox and Dr. A. E. Martin showed in 1934[1] that in addition to the normal type of diamond, which is always optically anisotropic, there is a rarer type which is much more nearly isotropic and which is more transparent both to infra-red and to ultra-violet radiation.

Observers of the diffuse scattering of X-rays by diamond[2, 3, 4, 5] have not hitherto stated which type of diamond they used. We have recently, through the kindness of Prof. W. T. Gordon, had the opportunity of examining some of the diamonds actually used by Robertson, Fox and Martin, as well as a number of other, smaller diamonds. Several of these diamonds, which were classified[1] as being of the rarer, "transparent" type II, gave results which were quite different from those obtained from type I diamonds. It would appear that the effects previously reported have always been those typical of the normal variety; these we propose to describe first.

The best photographs have been obtained with a small octahedral crystal, mass 1 mgm., using copper $K\alpha$- and β-, iron $K\alpha$- and β-radiations. Laue photographs have been taken at small intervals over a range of up to $\pm$ 20° from the Bragg angle on either side of the {111} {220} {113} [{331} and {004}] planes. The measurements on each series of photographs, when plotted on appropriate reciprocal nets, give in accurate detail the shape and extent of the diffracting regions around the reciprocal lattice points. From the data we find that these points are each surrounded by a small, roughly spherical region of diffuse ("primary") scattering, which only extends to about 3° from the Bragg angle, but that there are, in addition, regions of very sharp, intense ("secondary") diffraction along some or all of the reciprocal [100] [010] [001] axes. There are six such 'horns' extending in reciprocal space from the (111) points, more than half-way across the Brillouin zone in each case. The well-defined streaks, and triangles of sharp spots observed on photographs of diamond in various orientations correspond with great accuracy to the sections of these 'horns' by the sphere of reflexion. It is, however, an extraordinary fact, not as yet explained by any theory, that the {220} and {113} points in reciprocal space are not accompanied by six horns, but only by four. For the (220) and (113) points the [001] horns are missing, for the (202) and (131) points the [010] horns are missing, and the [100] for the (022) and (311) points. These results have been confirmed on crystals definitely classed by Robertson, Fox and Martin as being of type I, including diamond D 23, which showed unusually high photo-electric conductivity for that class.

Diamonds of type II show what we have called "primary" diffuse scattering, but the "secondary" effect is entirely missing. There are no sharp streaks, no triangles of sharp spots around a diffuse centre; only the diffuse centre appears, this being somewhat more persistent than in type I. Thus in the reciprocal net corresponding to type II diamonds, the horns of strong diffraction along the cube directions do not exist, either for the (111) or for any other points, so far as could be ascertained. Otherwise, the Laue pictures of the two types of diamond are identical, allowance being made for the very different shapes and sizes of the crystals used.

In the photographs illustrating the ordinary

h g f e

Top row: Diamond, Type I. Bottom row: Diamond, Type II.

diffraction from the (111) plane in various orientations, (*a*)—(*d*), and its modification in the transparent diamonds, (*e*)—(*h*), the photographic film has been placed either *normal to the reflected beam*, as in (*a*) (*e*) (*b*) (*f*), or at 10° to the incident beam, as in (*c*) (*g*) (*d*) (*h*). In (*a*) and (*e*) the crystal is set at θ_B and in (*c*) and (*g*) at $-\theta_B$, where θ_B is the Bragg angle of incidence for iron $K\alpha$ radiation and the (111) plane (28·05°). In these photographs, rings appear around the (111) reflexion, due to diffraction of the monochromatic reflected beam by the black paper covering the film-holder[6]. These rings, which are evidence both of the intensity of the reflected beam and of the accuracy of the crystal setting, disappear when the angle of incidence θ is more than $\pm 0{\cdot}3°$ from θ_B. Hence they are not present in photographs (*b*) and (*f*), where $\theta = \theta_B + 1$, or in (*d*) and (*h*), where $\theta = -(\theta_B + 2)$. The most remarkable difference between the two types of diamond illustrated by these photographs is that type I gives, in addition to the ordinary (111) reflexion, a diffuse spot accompanied by streaks or surrounded by a triangle of sharp spots, [in (*c*) the triangle is due to iron $K\beta$ radiation, the $K\alpha$ triangle being coincident with the Laue-Bragg reflexion], whereas in type II the (111) reflexion is accompanied only by a diffuse spot, without streaks or triangle. Another important difference is that type II diamonds are much better monochromators than ordinary diamonds (to judge from the intensity of the 'paper' rings), owing partly to the absence of extinction[1], and partly, no doubt, to the almost complete concentration of reflected radiation into a single nearly cylindrical beam.

It may be that what we have called the "primary" and "secondary" diffuse phenomena have different origins; that is a matter for further experiment. The investigation of the diffraction from different diamond planes was undertaken principally in order to find out whether the distribution of scattering power around the various reciprocal lattice points was the same, as the Preston–Bragg block theory would indicate, or different, as allowed by the Faxén–Waller heat theory[7]. Differences *have* been found, but they are not differences which are permissible according to the theory. Moreover, the compltee disappearance of the streaks and triangles in the diamonds of type II definitely eliminates the possibility of these "secondary" effects being due to thermally excited lattice vibrations. Any adequate explanation of the "secondary" spots and streaks (as distinct from the "primary") must account both for the differences between different planes in type I and the absence of the effect in type II.

Increased Yield of Nucleic Acid-like Substances from Irradiated Yeast

EVIDENCE that yeast irradiated with full ultra-violet light produces nucleic acid-like proliferation-promoting factors[1] led us to compare the yield of nucleic acid from irradiated and non-irradiated yeast in the following experiments.

Starch-free yeast (*S. cerevisiæ*, Fleischmann bakers' strain) was suspended at 300 gm. per litre in distilled water or 1 per cent dextrose. The suspension was divided into two fractions, one of which was irradiated with full ultra-violet from a Hanovia quartz mercury arc until half or more of the cells were killed, while the other was kept at the same temperature without irradiation. Nucleic acid was then prepared from both portions by the method of Johnson and Harkins[2].

In all, three preparations were made. The yield of crude nucleic acid from irradiated yeast (4·5–8·5 gm. per 300 gm. of yeast) was, in each case, greater than that from non-irradiated yeast (3–4 gm. per 300 gm. of yeast). Ultra-violet absorption spectra showed the typical maximum at 2600 A. characteristic of nucleic acids and their derivatives[3]. The extinction coefficient

of the nucleic acid from irradiated yeast was slightly higher than that from non-irradiated yeast, despite the greater yield of the former.

The third preparation was tested for growth-stimulating activity on cultures of yeast grown in rocker tubes in Reader's medium according to the usual techniques[4]. Both the preparation from irradiated yeast and that from non-irradiated yeast showed growth-stimulating activity, contrary to our previous findings for purified nucleic acid[5]. The activity per unit weight of the preparation from irradiated yeast was about twice as great as that from non-irradiated yeast, from which one may deduce that the proliferation-promoting activity was not due to nucleic acid as such but to contaminants (possibly closely related chemically) in the crude preparations.

Distribution of the Double Linkings in Irone

THE formulation of irene as 1 : 1 : 2 : 6-tetramethyltetralin[1] has recently been established synthetically by Bogert and Apfelbaum[2]. On the basis of this formulation of irene and the production of ββγ-trimethyl pimelic acid by ozonization of irone, structural formulæ have been postulated for this ketone by Ruzicka and his co-workers[3]. Two of the postulated structures contain the chromophoric system $C = C - C = C - C = O$ which should therefore give rise to a characteristic absorption spectrum.

We have recently prepared a specimen of irone from oil of orris and having ascertained that it had the appropriate constants and yielded the characteristic *p*-bromophenyl-hydrazone, we examined its absorption spectrum. This was found to exhibit an intense band at 2280 A. ($\log \varepsilon = 4{\cdot}08$) and an inflexion near 3080 A. ($\log \varepsilon = 2{\cdot}03$), the two together being characteristic of an αβ-unsaturated ketone. The location of the intense band indicates the presence of a monosubstituted αβ-unsaturated ketone[4] (probably $R.CH = CH - C(R) = O$) and clearly shows the $C = C - C = C - C = O$ structure to be absent. This inference is supported by the fact that the absorption spectrum of α-ionone (λ max. 2285 A.) is almost identical with that of irone (λ max. 2280 A.).

A full account of these results will be published elsewhere.

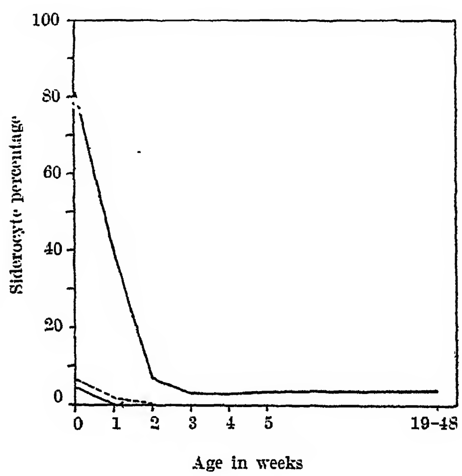
Siderocytes: a New Kind of Erythrocytes

IT is generally known that the presence of iron in the hæmoglobin molecule cannot be detected by the usual histochemical tests, such as the Prussian blue reaction with potassium ferrocyanide. As a consequence, tests for the presence of 'free' or easily detachable iron have scarcely been used in hæmatology.

I have recently investigated the anæmia associated with the recessive gene for flexed-tail and belly-spot in the mouse (*Mus musculus* L.)[1]. The anæmia is of a normocytic hypochromic type; it is severe at birth, but disappears more or less completely during the first few weeks of life; it can be shown that this improvement is inextricably linked up with the transition from the megaloblastic erythropoiesis of



PERCENTAGE OF SIDEROCYTES IN FLEXED-TAILED MICE (HEAVY LINE), NORMAL MICE (THIN LINE) AND NORMAL RATS (DOTTED LINE).

the fœtus to the normoblastic erythropoiesis of the adult, a process which in the mouse, as in the rat, largely takes place after birth.

It has recently been found that newborn flexed-tailed mice have numerous red cells which give the Prussian blue reaction for iron. (Blood films fixed in absolute methyl alcohol were treated with a freshly prepared solution of 1 per cent potassium ferrocyanide in 1 per cent hydrochloric acid at room temperature for 3–5 minutes and counterstained with Biebrich scarlet; the iron reaction is complete after one minute; identical results are obtained with hydrochloric acid concentrations down to 0·05 per cent; with 0·02 and 0·01 per cent hydrochloric acid, only a fraction of the cells will stain.) The 'iron cells' or 'siderocytes' do not stain diffusely, but show blue granules which vary in number from one to a dozen or more and in size from fairly large blobs down to the finest dust-like stipples; no such structures are visible in cells stained with Biebrich scarlet alone or with one of the ordinary hæmatological stains. As shown in the accompanying graph, the percentage of siderocytes diminishes rapidly with age; their reduction in numbers takes place at about the same rate at which the anæmia improves.

It was afterwards discovered that the presence of siderocytes is a normal feature in the embryonic life of the mouse; about 4 per cent are still present

at birth, while by the end of the first week siderocytes have nearly disappeared from the circulation. I am not certain whether in normal mice siderocytes are altogether absent later in life; it is difficult to be sure whether a very occasional dark stipple is or is not an artefact; if siderocytes are still present later in life, their frequency does not exceed 1 : 1,000 red cells. Siderocytes have also been found in new-born normal rats (*Rattus norvegicus*); their decline in number seems to be somewhat slower than in the mouse. Work is under way to discover whether the presence of siderocytes is a feature confined to the embryonic life of rodents.

The iron-containing compound in siderocytes is apparently distinct from the hæmosiderin pigment found in various pathological conditions, which s a brown granular substance visible in unstained preparations; in the majority of cases it is a breakdown product of red cells and has never been found inside intact erythrocytes in the circulation. The most likely suggestion is that normal mouse and rat embryos, and in a grossly exaggerated form flexed-tailed mice, partly furnish their red cells with a hitherto unidentified precursor of hæmoglobin, from which the iron can easily be split off. A less likely interpretation is that the easily detachable iron in siderocytes is the result of an unknown type of hæmoglobin breakdown taking place within the erythrocytes. The relation of the iron-containing compound in siderocytes to the 'labile iron' in blood studied by Legge and Lemberg[2] is uncertain.

A detailed account of this work will be published elsewhere.

Breeding of Xenopus in the Laboratory

Xenopus lævis is specially favourable for certain types of bio-assay. It is suitable for assay of gonadodesmic[1] extracts[2]. The clawed toad is the only satisfactory test animal for assay of melanophore-stimulating substance, that is, *B* substance [3, 4, 5]. The Hogben test for pregnancy is undoubtedly by far the most economical of those put forward so far, and its reliability is well established [6, 7, 8, 9]. The toad is easily kept in good condition and is an ideal laboratory animal. At the present time the drawback to its use is the difficulty of importing it from the natural habitat. Fortunately, however, Xenopus in good condition[7] ovulates at any time in response to injection of gonadodesmic extracts. So it is possible to produce progeny in large numbers and as required. We adopted the following procedure with successful results.

An injected male and an injected female were placed in a flat-bottomed dish. Coupling occurred within twenty-four hours with the production of fertilized eggs[10]. These were then transferred to a tray kept just under the surface of the water of an aerated aquarium. The temperature of the aquarium was about 22°, and its minute flora and fauna were typical of a well-stocked freshwater pond in Great Britain. Water from a number of other well-stocked aquaria trickled through the aquarium bringing in plankton and keeping the water free from breakdown products. When the eggs hatched young larvæ were transferred from tray to aquarium. Under these conditions tadpoles continued their development through metamorphosis to young adults. The latter were then fed daily with finely chopped fresh liver or muscle. They grew fast—12 months after oviposition the average weight was 9–10 gm. and the body length 4–5 cm. At this stage the toads are easily handled, and can be used for assay of *B*-substance and gonadodesmic extracts. They can replace the frog for many experimental purposes. The tadpoles, which can be obtained at any time of the year, could be used for assay of thyroid and thyrodesmic extracts.

Plankton as a Source of Food

WHILST it is correct to say that on occasions concentrations of algæ in eutrophic lakes and reservoirs will be very high, it should be remembered that these peaks of production are of short duration. Again, of the dry weight of the diatom *Fragilaria crotonensis*, estimated at 110 tons, quoted by Walker[1], approximately one half is silicon. Further, the fine mesh of any netting that would be necessary to retain algæ would add enormously to the difficulties of collection. I am, therefore, doubtful whether attempts to use phytoplankton as food would be practical or economic, and, in my view, it would be better to investigate the possibilities of large-scale collection of marine zooplankton, as advocated by Hardy[2].

A rich zooplankton is found seasonally in fresh water, but although I have eaten Crustacea tow-netted both from Lough Derg, Ireland, and Windermere and found them not unpleasant, I feel sure that the collection of these smaller forms would present greater difficulties than that of the bigger marine planktonic Crustacea.

RESEARCH ITEMS

Control of Gonorrhœa

In an address before the American Medical Association on June 6, W. Bromme claimed that complete control of gonorrhœa is promised by a new treatment. Complete cures in three days of one hundred out of one hundred men were achieved by sulphathiazole treatment. Large doses of the drug, averaging sixty grains a day, were continued in the same dosage for forty-eight hours after the patient is apparently cured. The patients in Dr. Bromme's series were crane operators, foundrymen and others employed in heavy industries. None of them lost a single day from work while taking the treatment. The sulphathiazole is given by mouth. Mild nausea in twenty-three patients and fever of 100·6° F., not enough for most persons to know they had fever, in six patients, were the only reactions to the drug. The author believes that large doses of the sulpha drugs at the start of treatment should be used not only for gonorrhœa but also for meningitis, pneumonia and streptococcus infections. He considers that fewer reactions and more effective cures will result from such doses than from the customary small, often-repeated doses. The small, often-repeated doses of these drugs, which many medical men have used on a cautious basis, provide a chance for the patient to become sensitized to the drug, with resulting untoward symptoms requiring stopping of the drug, and also give the germs a chance to become used to the drug, so that it does not affect them. This is probably the basis of the 'sulphanilamide resistance', which has been reported as a cause of failure of the sulpha drugs in some cases in which patients did not get well even after long treatment.

Artificial Synthesis of Wheat ($n = 42$)

By combining two dissimilar relatives of wheat, E. J. Britten and W. P. Thompson, of the University of Saskatchewan, have obtained a 'synthetic' hybrid plant closely resembling the common cultivated species (*Triticum vulgare*) (*Science*, May 16). Ordinary cultivated wheat has forty-two chromosomes. It is commonly believed that it originated as a natural hybrid between two other species with lower chromosome numbers. To test this theory, Dr. Britten and Prof. Thompson hybridized a fourteen-chromosome species of wheat (emmer, *Triticum vulgare*) with a wheat-like grass (*Ægilops speltoides*) with only seven chromosomes. This hybrid plant had twenty-one chromosomes, but was completely sterile. The authors then treated the hybrid intensively with a solution of colchicine, making daily injections with a hypodermic needle. This eventually resulted in the formation of heads of grain that had the chromosome number of cultivated wheat (forty-two) and were fully fertile. In external characters, also, the artificially produced plants showed considerable resemblance to ordinary wheat.

Dominance in Gossypium

S. C. Harland and O. M. Atteck (*J. Gen.*, **42**, 21–47; 1941) report the results of a series of backcrossing experiments involving the crinkled mutant of cotton. They believe that dominance has been obtained to crinkled in *Gossypium hirsutum*, *G. purpurascens* and *G. Taitense* by the method suggested by Fisher. In these species, modifiers have been selected in the heterozygote towards modification of the dominance relations and amelioration of the crinkled character. In *G. barbadense*, *G. tomentosum*, and *G. Darwinii*, there is a normal allelomorph of great dominance potency as postulated by Haldane's theory. The recessive condition in these species is relatively unmodified. A discussion of the Fisher effect is given.

Leaf Colours of Coleus

C. L. Bonge (*J. Gen.*, **42**, 191–196; 1941) has published the results of his experiments to elucidate the various colours of commercial Coleus. There is a multiple allelomorph series *Pp–gp*. *P* determines purple colour, which is dominant to p_g which gives green leaves; while the recessive *p* gives a central pattern of colour to the leaf. At another locus, *I* gives a blue-green colour and its allelomorph *i* gives a yellow-green colour to the leaf. Interaction of expressions between these non-allelomorphic genes is observed in certain combinations; for example, *Pp-gI* gives a 'grey' leaf colour, whereas *PpI* gives rise to purple leaves.

Biology of Indian Rust Fungi

Life-histories of two rust fungi attacking the forest tree *Pinus longifolia* have been elucidated by the work of K. Bagchee (*Indian For. Rec.*, Bot., **1**, No. 7, 247; January 1941). *Peridermium himalayense*, on the stem of the tree, is related with a new species of Cronartium upon a species of Swertia as host, as shown by cross inoculation with teleutospores. The other fungus, *P. orientale*, attacks the pine needles, and is the alternative stage of *Coleosporium campanulæ* on *Campanula colorata*. It is interesting that another physiological form of this fungus on *Campanula canescens* cannot induce the æcidia to appear on the pine host.

Solubility Effect in Benzene

Krauss and Fuoss since 1933 have shown from conductivity, freezing point and dielectric constant measurements that in cases where acid-base reactions are not involved, the properties of electrolytic solutions depend primarily on the dielectric constant of the solvent, and these properties have been interpreted on the basis of coulomb forces between ions, ion pairs and triple ions. A. W. Vernon, W. F. Luder and M. Giella (*J. Amer. Chem. Soc.*, **63**, 862; 1941) have measured the effect of tetramethylammonium picrate and nitrate on the solubility of tetrabutylammonium iodide in benzene, a solvent of low dielectric constant. Although a common ion is involved, the solubility of the iodide increases rapidly as the picrate or nitrate is added. In the case of the picrate, the solubility of the iodide increases linearly with the picrate concentration. The results indicate that there can be very few single ions present and that the salts are associated in the solvent of low dielectric constant ($D=2·28$). In the case of ethylene dichloride ($D=10·23$) the solubility effect is normal. In benzene there may be association to triple ions, quadripoles and even higher multiples. The conductance measurements show a minimum at

small concentration, the conductance slowly rising as the concentration is increased. The effects are too complex for quantitative treatment at present, but they are in qualitative agreement with the theory. Thus, the solubility of the iodide at first increases more rapidly on addition of nitrate than with the picrate, and the theory indicates a higher association when symmetrical ions are involved.

The Acetyl Radical

THE presence of the acetyl radical, CH_3CO, as an intermediate in the photolysis of some carbonyl compounds, and its instability at higher temperatures have been observed. Not only may it decompose into a methyl radical, CH_3, and carbon monoxide, but it may also disappear by some other reactions which do not liberate carbon monoxide. The carbon monoxide yields in the photolysis of compounds which can form an acetyl radical might be expected to show similarities in their variation with temperature. H. W. Anderson and G. K. Rollefson (*J. Amer. Chem. Soc.*, **63**, 816; 1941) have tested this point by measuring the dependence of the carbon monoxide yield on temperature from 0° to 140° in the cases of the photolysis of acetone, diacetyl and acetyl bromide vapour. The conclusion is reached that acetyl radicals are formed with such high energies that some of them decompose spontaneously into methyl and carbon monoxide. If this initial surplus of energy is lost by collisions, the acetyl radicals may either decompose or combine to form diacetyl, the decomposition reaction becoming increasingly important above 50°.

Hydrolysis of Methyl Acetate

ONE of the classical examples of a first-order reaction is the hydrolysis of methyl acetate in presence of a large excess of water, in which the reverse reaction is also neglected: $CH_3.COO.CH_3 + H_2O = CH_3.COOH + CH_3OH$. By working in acetone as a solvent instead of water, where the water concentration changes materially during the reaction, and using sulphuric acid as catalyst, H. B. Friedman and G. V. Elmore (*J. Amer. Chem. Soc.*, **63**, 864; 1941) find that the reaction is really of the second order, the velocity being proportional to the ester and water concentrations. It was also found that the velocity coefficient for the second-order reaction was more constant when the reverse reaction (esterification) was taken into account, so that the velocity equation is: $dx/dt = k(a-x)(b-x) - k'x^2$, where a and b are the initial ester and water concentrations and x is the concentration of acetic acid produced by hydrolysis. The value of the equilibrium constant, $K = k/k'$, was found from the equilibrium concentrations in presence of excess of water. Then if $K' = 1/K$, the velocity equation is $(1/k)\ dx/dt = (a-x)(b-x) - K'x^2$, from which the values of K were found from the integrated form of the equation.

Activity of Thallous Chloride

THE solubilities of thallous chloride in presence of potassium chloride in solvents composed of ethyl alcohol and water in varying ratio have been measured by E. Hogge and A. B. Garrett (*J. Amer. Chem. Soc.*, **63**, 1089; 1941), and the results considered from the point of view of the activity of the thallous chloride. If $m_\pm$ is the mean molality, $\sqrt{m_+ m_-}$ and I the ionic strength of the solution, the graph of $\log m_\pm$ against $\sqrt{I}$ should be a straight line; or, if this is not the case, the limiting slope should (for infinite dilution or $I=0$) have a theoretical value given by the Debye-Hückel theory of strong electrolytes. This theoretical value of the limiting slope was not found in any case. The first-order correction for mean distance of ionic approach also gave (as is often found in other systems) impossible negative values. Since thallous chloride is a moderately weak electrolyte, however, a correction for ionic association must be made; and it was found that when this was applied the results were satisfactory. The effect of the dielectric constant of the solvent was in qualitative agreement only with the theory of Born, and the deviations increase as the dielectric constant decreases.

Stress and Strain Relation for the Atomic Lattice of Iron

S. L. Smith and W. A. Wood (*Proc. Roy. Soc.*, **178**, 93) have measured the lattice spacing of iron by X-ray methods while applying tension to the specimen, and have thus obtained a stress–strain relation for the atomic lattice. The spacing was measured at right angles to the stress and the changes are therefore compared with the lateral contraction observed externally. Up to the yield point the contraction is proportional to the stress; beyond this point the contraction slows down and eventually reverses into an expansion. It was further found that a permanent expansion may be produced by stressing beyond the yield point. It is concluded that the observed effect of stressing beyond the yield point was due to the superposition of an elastic contraction, comparable with that observed externally, and a lattice deformation leading to expansion. Further experiments showed that the permanent expansion after loading took place along the direction of stress as well as at right angles to it, and hence results in a decrease of density. Recovery of the lattice was produced by gentle heat treatment at temperatures well below those necessary for recrystallization.

Nova Cygni III (1920)

THIS extraordinary star increased its brightness, probably in little more than a fortnight, by a factor of more than 250,000, the greatest rise ever recorded for an ordinary galactic nova. A recent monograph by R. B. Baldwin (*Publ. Obs. Univ. Mich.*, **8**, 61; 1941) gives a critical discussion of its spectrum through maximum light and for the six weeks thereafter during which spectroscopic observation was practicable at Ann Arbor. The general development of the star followed that observed in other novæ: great quantities of material were ejected in shells from the central star. In this case no less than eleven shells were detected, their velocities of ejection varying from 400 km./sec. for the first to nearly 3,000 km./sec. for the last. An unusual feature shown by almost all the various spectra is the extreme diffuseness of their absorption lines and emission bands, suggesting a wide range of atomic velocities in the individual shells. Another abnormal development noted by Baldwin is that a year after the outburst (by which time the star showed a visible disk) the velocity shown was not the expected 750 km./sec. of absorption II, the principal feature which had dominated the spectrum since three days after maximum, but 1,200 km./sec., corresponding to absorption V, a relatively transitory feature of the spectrum.

BIOLOGY OF EPIDEMICS*

By Prof. W. W. C. Topley, F.R.S.

THE universe of study which to-day faces the epidemiologist is not, in its essence, composed of a number of cases of a clinically recognizable disease, with a distribution that varies in an observable way in space and time. It is composed of a variety of biological species, some acting as parasites and some as hosts. The parasites may be viruses, or bacteria, or protozoa, or worms. The hosts may be men, or animals, or insects, or plants. The parasite may pass from host to host by direct contact, by indirect mechanical contact, or through the agency of an insect vector. In whatever way it passes, the main factor that determines the occurrence and type of an epidemic prevalence is the frequency of its passage.

If all relevant environmental conditions are held constant, and susceptible hosts are added at a high and steady rate to an infected herd, a steady rate of mortality is attained, with no major waves or fluctuations. If, with a steady rate of addition, the closeness of contact between host and host is changed, increased closeness of contact is followed by the propagation of a major epidemic wave, and decreased opportunity for contact by a rapid fall in the mortality rate. These experimental observations have many analogies in the recorded prevalence of infectious disease under natural conditions.

During an epidemic prevalence the average resistance of the hosts rises with length of exposure to risk; in part because of the elimination by death of the more susceptible individuals, in part because of the natural immunization of survivors. The resistance attained in this way, though sometimes high, is never absolute. We can, in many cases, attain the advantages of natural immunization, without its risks, by an appropriate method of vaccination.

Differences in severity between different epidemics of the same disease are in part accounted for by biological differences between various strains of a single parasitic species, between different races of a single species of host, or between different races of a single species of insect vector. The biological characters that determine the ability of a parasite to spread from host to host are not identical with the characters that determine its ability to multiply rapidly in the host's viruses, so that virulence and infectivity may vary independently.

In attempting to control epidemics we always strive, in one way of another, to decrease the probability of the passage of the causative parasite from an infected to a susceptible host. We may do this by changes in the distribution of the hosts at risk, or by lessening the population density of an essential insect vector, or by reducing the proportion of susceptible hosts by artificial immunization, or in many other ways. In no case is it necessary, by our own action, to reduce the probability to zero. The epidemic system is in unstable equilibrium. If we tip the balance far enough in favour of the host, the system itself will do the rest, and the disease will tend to become very infrequent, and may sometimes disappear.

* Substance of the Croonian Lecture delivered before the Royal Society on July 17.

LUMINESCENT MATERIALS*

FOR some years before the War there had been increasing interest in the fundamental and applied aspects of the luminescence of solids concurrently with a search for new and better luminescent solids by commercial firms. The possibilities in war of such materials are considerable; whilst it is obviously impossible now to discuss applications in the Services, there are many which can be made of value to the public at large. Unfortunately, at the outset of war, commercial development outran technical knowledge in the materials presented for sale to the public, and the consequent crop of failures aroused public prejudice against them.

The subject has been under investigation by a specially formed expert committee of the Civil Defence Research Committee, which has now issued a bulletin largely to explain how luminescent devices can best be used in present circumstances. The work of the Committee has covered both a comprehensive study of the theory of the subject including, in particular, the laws of phosphorescence; an attempt to make good the deficiencies in luminescent materials and improve their method of manufacture; and an indication of possible applications. The bulletin in particular names the materials available and their properties, sources of irradiation, and enumerates a large number of possible applications, though the list is by no means exhaustive or complete.

The theory of the subject has been studied particularly by Dr. J. T. Randall at the University of Birmingham in recent years, where a method has been developed of studying the electronic 'traps' in luminescent solids. Such solids owe their properties to the presence of minute traces of an impurity, and their preparation depends on the addition of an activator to the pure matrix materials followed by a heat treatment which causes an intimate association of impurity atoms and matrix lattice.

The commoner luminous pigments fall into two main classes: (i) zinc and zinc cadmium sulphides; (ii) alkaline earth sulphides. The former have a high fluorescent brightness but relatively short periods of afterglow; the latter exhibit lower initial brightness but have longer periods of afterglow. To make these materials really useful in practice there must be uniformity in behaviour from batch to batch and, in the long run, their properties must be improved. In

* Luminescent Materials and their War-time Uses. Bulletin C.17, Ministry of Home Security, Research and Experiments Department, Princes Risborough, Bucks.

simple language, the number of 'traps' has to be increased and a means of control of the rate of their discharge found. It is to this end that an understanding of the theory of phosphorescence is required; success will mean that better powders are possible. The stimulus to manufacturers given by the existence of the Committee is said already to have resulted in a marked improvement of the commercial products.

But it is not enough to make the active products; they have to be incorporated into paints, plastics or enamels, and shielded in a manner which gives protection against weathering if they are to be exposed out of doors. In addition, the greatest care has to be taken during the incorporation lest the activity of the phosphors be lessened.

The problem has still another side when fluorescent materials are used, since these have to be continuously energized by ultra-violet radiation. The types of source of this which are available are indicated in the bulletin. A minor point here is the relatively short useful life of the argon lamp: probably research is already going on in other quarters to improve this. It is suggested that, could this be realized and the lamp 'mass-produced', a great stimulus would be given to the use of fluorescent materials rendered visible by such means.

It is clear that the scope of what at first sight might appear to be a limited investigation is in reality quite wide and that the existence of the Committee is fully justified. It is to be hoped that the results of its work will be made available at least in quarters where this can be applied for the public weal. This is the more desirable since it is known that luminescent materials were widely applied in France and Germany last winter, whereas little use was made of them in Great Britain: this in spite of the fact that there was no lack of knowledge of them in scientific circles in England.

THE ROYAL OBSERVATORY, GREENWICH

Annual Report of the Astronomer Royal

The annual report of the Astronomer Royal, just published, refers to the work of the Royal Observatory during the period May 1, 1940–April 30, 1941. To those who know the position of the Observatory, in the midst of military and industrial objectives, it will come as no surprise that much of the work has been curtailed by enemy action. The last report mentioned the dismantling of much of the optical apparatus; most of the mirrors and lenses have now been sent away from Greenwich for safety. Since heavy bombing of London started last September, night observations have been impossible on such of the telescopes as had not already been dismounted at the outbreak of hostilities; in fact, the only observing programmes still carried on at Greenwich are daylight ones, namely, the routine meteorological work and the photographic and visual solar observations.

The public time service functions well from two emergency outstations, as the familiar 'six pips' regularly testify. The Rugby rhythmic signals, however, in present circumstances fall short of the high precision needed for control of frequency standards, though they are, of course, quite adequate for navigation. Rating of chronometers and watches and their issue to the Royal Navy continue as usual, though the entire establishment concerned has been moved for the second time in two years.

Work has ceased on the Airy transit circle after continuous observation with this instrument for ninety years. More than 650,000 observations have been made with it, forming the most important contribution from a single instrument to fundamental positional astronomy. The new reversible transit circle which is to take its place has obtained nearly 10,000 transits during the last three years. When observing ceased in September 1940, the work of determining the division errors had been completed and an investigation started on the irregularities of the pivots. These latter have already been found to be extremely small.

The photoheliograph and spectrohelioscope observations show the expected decline in solar activity from the 1937–38 maximum, the sunspot frequency having dropped to about half that at maximum. Nevertheless, twenty-one large groups of spots occurred, six of them being later associated with magnetic storms. One of these latter, that of March 1, 1941, ranks high among the most severe disturbances of the past ninety years. The associated spot could not be extensively observed because of cloud, but the number of short-wave radio fade-outs occurring during its central meridian passage suggests that it was chromospherically very active. Over the year as a whole, however, both chromospheric eruptions and radio fade-outs were few.

The meteorological department of the Observatory has celebrated its centenary of routine observations. Features of the year's weather include an August drier than any for 122 years, and a period from December to April during which each month was considerably colder than normal, the temperature in the Stevenson screen never reaching 59° F. for the whole five months.

Discussion of the photographic material, comprising nearly 3,000 plates, obtained during the 1931 opposition of Eros, is now practically complete. The solar parallax deduced from these observations at stations all over the world is $8{\cdot}790'' \pm 0{\cdot}001''$, the previously accepted value being $8{\cdot}80''$.

The "Nautical Almanac" office continues its essential work, though it has had to contend with the destruction by fire of the whole of the type and plates for all its publications except the "Astronomical Navigation Tables". The consequent delay in publication is being rapidly made good, in some cases by using photographic reproduction in lieu of printing from type.

Astronomers all over the world will join in sympathizing with the Astronomer Royal and his staff on the interruption of many of their long-established programmes, and in congratulating them on their maintenance of essential services throughout a very trying period.

FORTHCOMING EVENTS

SATURDAY, JULY 26

BRITISH PSYCHOLOGICAL SOCIETY (at Tavistock House, Tavistock Square, London, W.C.1), at 10.30 a.m.—Discussion on "Psychological Problems of Air Raid Shelters and Evacuation".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN CIVIL AND MECHANICAL ENGINEERING—The Secretary, Woolwich Polytechnic, Woolwich, London, S.E.18 (July 30).

ASSISTANT LECTURERS (TWO) IN SCIENCE, MATHEMATICS AND DRAWING in the Halesowen County Technical School—The Clerk to the Halesowen Local Higher Education Committee, 21 Great Cornbow, Halesowen, Worcestershire (July 30).

PHYSICIST FOR THE BRADFORD REGIONAL RADIUM CENTRE—The House Governor and Secretary, Bradford Royal Infirmary, Bradford.

REPORTS AND OTHER PUBLICATIONS

AN INTERNATIONAL INTELLIGENCE FRONT

FOLLOWING on the establishment last November by the Ministry of Labour of an International Labour Branch as a central agency for making the best possible use of the services and labour of Allied and other friendly foreigners in Great Britain, the industrial registration of friendly aliens which the Ministry commenced on June 9 is a belated step to enlist many valuable heads and hands in our war effort, with the success of which they are as much concerned as ourselves. The man-power position may indeed well make us anxious to secure the very important contribution to our war effort which should be possible from the quarter of a million of these refugees, many of whom could make expert contributions in particular fields.

While, however, the Government has now realized the damage to our national war effort which was done by the policy of internment, which although an urgent necessity at the time of the fall of France has long outlived the emergency, there are few signs that either the Government or the nation realizes the moral consequences or the psychological opportunities which were open to us in this field as soon as the migration from Germany under Nazi persecution commenced. These consequences and opportunities have been well portrayed by Sebastian Haffner in a penetrating survey of the German nation and its leaders and of the possibilities and objectives of Allied propaganda which appeared last year under the title "Germany : Jekyll and Hyde"*. This book is a damning indictment of the policy pursued in the democracies, including the United States, towards such refugees, even before the outbreak of war.

This arresting picture of the deplorable effect of the failure of the democracies to realize before the War the significance of this migration from Germany and, by adopting a generous policy, to establish an anti-Nazi stronghold beyond the reach of the Gestapo is not, however, solely one of opportunities irretrievably lost. It gains fresh interest as the growing stress of the conflict compels us to explore more thoroughly and exhaustively all our moral and material resources. We can no longer, it is true, confront the German Reich with not merely one hundred thousand but a couple of million from among its best, most intelligent and most educated citizens, with all the repercussions on German moral and material reserves which a migration on that scale involves. The Evian conference closed the door on that prospect, which the Nazis were astute enough to fear and to exploit when the danger passed.

* "Germany : Jekyll and Hyde." By Sebastian Haffner. Trans. by Wilfred David. Pp. 320. (London : Secker and Warburg, Ltd., 1940.) 8s. 6d. net.

For all the tragedy of Evian, however, Nazi propaganda is taxed to the utmost to conceal the fact that Germany entered the War as a thoroughly disunited nation and that large sections of her people fear victory more than defeat. This is still our great psychological opportunity. It can be seized only with the help of the *émigrés*, and that is the greatest contribution they can offer to our war effort.

It is still possible, however, to use this German anti-Nazi movement both in the fight against Nazism as well as in the subsequent necessary reconstruction of Germany. Far more significant than the formation from them of a German Freedom Legion would be, as Haffner suggests, the formation of a German Academy. The blow to Nazi prestige which such a step could deal is not to be underrated, and might be decisive in winning the War and in preparing the peace. Even more effective might be the utilization of the experience of internal German politics, the knowledge of German political psychology, and the underground ties with Germany which are represented by these *émigrés*.

Such an organization might well go farther. By supervising the refugees and their military, cultural and political organizations, it would serve as a link with the Allied Governments. It might elaborate plans for Germany's reconstruction and future constitution and establish semi-diplomatic relations with the opposition groups within Germany, through the neutral countries.

If these opportunities are to be seized and such possibilities realized, however, there must be a profound change in the attitude and policy of the Government and indeed of many of the ordinary citizens. The first step in a positive and constructive policy towards Germany is a constructive and positive policy to the German *émigré*. The great opportunity presented by the offer of co-operation of large numbers of German political intelligentsia, men of science and others, now living outside Germany, and of the many who, mortal foes of the Nazis, are numerous enough to form at least a symbolic kernel of a German army to fight by the side of the Allies, must be grasped. The refugees must not simply be treated with humanity; they must be harnessed to the common cause.

Important as is this political contribution, there is also the question of learning and scholarship represented by these *émigrés*, among whom is a high proportion of outstanding workers in science, medicine and literature. To this question and its implications Dr. Raymond B. Fosdick, president of the Rockefeller Foundation, once again makes striking reference in his review of the Foundation's work in 1940. Many of the brilliant men with whose work the Foundation was associated are now driven from the posts for which they were trained, debarred from their laboratories, some of them fugitives, some in concentration camps, many of them separated from their families or lost in foreign countries where they sought haven.

The sombre picture of the breakdown in international solidarity, which in the realm of scholarship, at least, had become a vital factor in progress, contained in Dr. Fosdick's review affords a background against which this question of the refugee or *émigré* must be viewed if we are to keep a true perspective. The conception of knowledge as an international responsibility has vanished from Europe. The free flow of ideas across boundary lines between laboratories and universities has dried up.

The condition of university life and standards on the Continent, Dr. Fosdick asserts, is now little short of appalling. Due to flight, imprisonment or disappearance, the number of professors in institutions has been reduced by at least 50 per cent. Over all the Continental universities hangs the pall of uncertainty and fear. The contact with contemporary life has been abruptly broken. Even when fundamental research is being continued, publication has largely been abandoned or postponed. In the social sciences such research as is carried on is confined to innocuous projects which have no relevancy to the present scene. Even neutral countries are under pressure to permit a totalitarian interpretation in teaching such subjects as economics, political science and sociology.

In such surroundings, as Dr. Fosdick reminds us, scholarship withers; nothing short of heroic struggle can keep it alive. It is only free men who dare to think, and it is only through free thought that the soul of a people can be kept alive.

Considerations such as these give pertinence to the suggestion of an *émigré* academy thrown out by Haffner, particularly if this is not limited to one nationality. The Rockefeller Foundation itself is indeed nobly striving to salvage some proportion of the productive scholarship of the refugees from the conquered countries. Two of its programmes, a placement programme from 1933 to 1939, and an emergency rescue programme in 1940, have endeavoured to protect the careers of scholars unable to continue work in their native lands. During the seven years ending in 1939, 775,000 dollars were appropriated by the Foundation on the first of these, about 500,000 dollars being allocated to American institutions where 122 individual scholars found places, 99 of whom were established in permanent positions by the end of 1939.

In 1940 the second rescue programme was instituted with the assistance of the New School for Social Research and, in the task of permanent

placement, by the Emergency Committee in Aid of Displaced Foreign Scholars. During 1940, on behalf of the refugee scholars endangered by the invasion of Scandinavia, the Low Countries and France, the Rockefeller Foundation made fifty-six grants totalling 266,350 dollars. The fifty-six scholars assisted included nineteen Germans, eleven French, seven Poles, five Russians, five Austrians, three Norwegians, two Spaniards, one Belgian, one Czech, one Italian and one Swiss. Among them were physiologists, biochemists, mathematicians, neurologists, statisticians, economists, historians, philosophers and philologists. One was a Nobel prize-winner and nearly all had international reputations.

Hopelessly inadequate as efforts of this kind may seem through the restrictions imposed on the occupied territories of Europe, they are not without value. At least they reveal the mockery of science and learning which parades in the vaunted New Order of Hitler, and how truly it would sound the death knell of culture and intellectual life. By themselves they are quite inadequate.

To accord to all aliens in sympathy with the ideals for which Britain is fighting the full status of allies with freedom of employment, domicile and movement is only the first step. Utilization of the services of the engineers, chemists, doctors and nurses at present waiting employment would demonstrate the solidarity of an international front against Nazism. The relief it would bring to our war effort is indeed the least of the consequences of such a step—every layman knows well how overburdened are medical men in general practice in almost every part of Great Britain.

What is above all required is a policy towards the *émigrés* which will enlist as fellow-workers and partners all in sympathy with the ideas and ideals for which we are striving and afford them full opportunity of making their own contribution to that end. That policy must be inspired by a large vision of the psychological possibilities, of the opportunities of a psychological war on Germany which could be carried on with such assistance, thus not merely shortening the war but assisting also to build a stable and better European order after hostilities have ceased.

To see in the presence of these foreigners, bitterly opposed to the Nazi regime and eager to fight with us to secure its overthrow, not dangers and hindrances to our war effort, real as some of the difficulties which attend an enlightened policy may be, to realize the counterpart to the Allied Governments already present in Great Britain which they represent, demands both courage and imagination. Without these and without magnanimity, such a war as this of ideas and of irreconcilable conceptions, of human values, of justice and of society cannot be won nor an enduring peace achieved. Given, however, the statesmanship alive to the human and moral issues involved, resolute to explore all the possibilities which the position of so many Allied Governments and political leaders from enemy or occupied countries offers us, and no less keen in its scrutiny of the dangers of treachery or abuse of privilege, decisive action greatly accelerating victory might well be taken. Bold and imaginative steps like the organization of some suitable institution where the great gifts and international reputations of many of these scholars could find ample employ might well set the stream of thought flowing across international frontiers once more, and shatter the pretensions of Hitler and the Nazis to stand even for a united Germany, let alone a wretched regime of slavery and tyranny imposed on one broken country after another. It would, moreover, add to our own effort all the inspiration which comes from a policy conceived in a spirit worthy of the great cause which we are pledged so deeply to defend and the ideals to which the free nations do homage.

THE CHURCHES CHALLENGED

A Challenge to the Churches

Religion and Democracy. By John Macmurray. (The Democratic Order, No. 9.) Pp. 63. (London: Kegan Paul and Co., Ltd., 1941.) 1*s*. net.

THE Churches have had so many "challenges" presented to them that they are becoming accustomed to take them as read, and this indifference is often justified by the ignorance of the challengers, but it is to be hoped that Prof. Macmurray's little book will have serious attention, for it is the cry from the heart of one who knows what Christianity has been and passionately believes in its creative power. In this pamphlet the author is conducting an argument on two fronts; he is pleading with his left-wing associates to realize that without Christianity there cannot be a socialist order which is also free, and he is trying to convince his fellow-Christians that the Church needs a new and drastic reformation.

The first of these theses rests upon an interesting and, as I think, convincing analysis of the tendency

of social evolution. The coming of large-scale State socialism is probably inevitable and, with it, the control by the State of the finances which in times past have been largely within the power of individual citizens. The religious sphere is the only one which can maintain itself independent of State control. The very possibility of democracy depends on the existence of a vigorous and almost universally accepted religion. If this condition be absent the State may profess the most extreme democratic aspirations but will be, in effect, a dictatorship. It appears to be Prof. Macmurray's opinion that this is what has happened in Russia. In an epigram which has perhaps prophetic truth he sums up his view by remarking: "Religion seeks to draw men into unity by love. Government seeks to compel them into co-operation by fear."

Bergson in his last great book, "Les Deux Sources", draws a distinction between static and creative religion, and though Prof. Macmurray does not refer to him, the fundamental idea on which the second of the theses rests is very much that of the French philosopher. The essential challenge to the Churches is that they have become the spiritual support of the old order, whereas if they had been true to the original gospel they would have been creating the new order. There is much salutary truth in the reproach, and I have no quarrel with the main contention; but it seems to me that some of Prof. Macmurray's statements in working out the idea are open to question. He suggests that Christian doctrine is the product of Greek philosophy to a much greater degree than history would warrant. It is strange that an eminent philosopher should object to the attempt to find a philosophical basis and formulation for a spiritual message. Most of all, it might be objected that he allows too little weight to the "other-worldly" elements in the New Testament. Christianity would be false to its deepest convictions if it came to hold that "in this life only we have hope in Christ Jesus". This is a small book which contains more matter for reflexion than most large ones; may it be widely read—and not only by members of the challenged Churches!

W. R. MATTHEWS.

ABORIGINAL TRIBES OF TRAVANCORE

The Travancore Tribes and Castes
Vol. 3: The Aborigines of Travancore. By L. A. Krishna Iyer. Pp. xxiii+176+54 plates. (Trivandrum: Government Press, 1941.)

THE late Dewan Bahadur L. K. Ananthakrishna Iyer will long be remembered as one of the pioneers of Indian ethnography, and his son, Mr. L. A. Krishna Iyer, of the Travancore Forests Department and at present in charge of the Ethnographic Survey of that State, is commendably following in his father's footsteps. His third volume of "The Travancore Tribes and Castes" has just been published. The first volume gave individual accounts of seven of the Travancore hill tribes, the second volume dealt with another eight tribes, and the present volume deals with all the fifteen comparatively and generally instead of severally.

Inevitably, no doubt, much of the previous information given is reiterated, and there are perhaps unnecessary duplications of tables and charts showing stature, cephalic index, etc., while the illustrations are in many cases repeated from one or other of the previous volumes. Ten pages are taken up with extracts from reviews in the Press and complimentary letters from individuals with regard to the contents of the first two volumes. There is, however, new material as well in the volume under review, apart from the comparative treatment. Thus there are a couple of pages on the blood-groups of Travancore tribes, in so far as figures are available. The results are interesting as suggesting three different strains among the South Indian aborigines, one in which group O constitutes about 50 per cent and A about 30 per cent, such as the Kadar, suggesting comparison with the Bushmen and Australians, another in which O is comparatively low, 20 per cent, while A stands at 60 per cent, the Paniyan, and a third, the Kanikkar, in whom the O group stands at about 50 per cent again, while A is less than 20 per cent and B is nearly 30 per cent. This is not a high percentage for B as figures for India in general run, but it is in marked contrast to both of the former groups.

A short chapter is also given to megalithic monuments, of which there are some good photographs. The author apparently inclines to Perry's view that megalithic monuments are everywhere to be associated with the search for gold on the part of "the archaic civilization". He quotes Newbigin to the effect that the uniformity of structure of megalithic monuments in India and Europe is accompanied by a corresponding uniformity of the skeletons contained therein, as all are dolichocephalic. The words used, however, do not seem to be actually Miss Newbigin's (her name,

too, is misspelled) and go farther than her actual text seems to warrant.

A chapter on racial affinities compares the views of various authorities. As elsewhere, the author modestly refrains from committing himself to any particular view, being content to sum up what others have stated. Other chapters deal with traditions, domestic life, exogamy, marriage, taboo, inheritance, etc., disposal of the dead, religion, and occupation and the clash of culture. The data set out have in many cases been given in the previous volumes when dealing with the tribes individually, but are here treated as a whole. The author occasionally leaves us in doubt as to his real meaning. Thus when he says that "the nephew of the Pulaya inherits the mortar and pestle and the youngest wife of his uncle" and takes his aunt to wife, presumably he means that the man marries his mother's brother's widow, as the system of the Garo tribe of Assam is adduced in comparison ; but it is nowhere made clear that he does not marry his father's brother's youngest widow, and we learn from vol. 1 that a Malapulaya may marry the daughter of his mother's brother or of his father's sister. A detailed note on the question would be worth publishing.

The issue of this volume completes the three volumes on the Travancore tribes, but the castes proper have not been touched in them, and it is much to be desired that the author should now proceed and deal with the castes. Most of the castes to be found in Travancore have been dealt with individually by Thurston and Rangachari in "The Castes and Tribes of Southern India", or by Mr. Iyer's own father in his "Cochin Tribes and Castes", so that a general approach on the lines of the present volume would be the most useful. Indeed a treatment of castes in this manner has possibly not yet been tried. Here is an admirable opportunity, and it is to be hoped that the Travancore State will not fail to make use of Mr. Iyer to complete a valuable series.

MOSQUITOES OF AFRICA

Mosquitoes of the Ethiopian Region
3 : Culicine Adults and Pupæ. By Dr. F. W. Edwards. Pp. viii+499+4 plates. (London : British Museum (Natural History), 1941.)

THE present is the third and final volume of a general monograph of the mosquitoes of tropical and subtropical Africa. The first volume (1936) by Hopkins dealt with the larvæ of the Culicine mosquitoes and covered both their biology and external anatomy. The second volume (1938) by the late Dr. Alwen Evans, gave a very detailed account of the Anopheline mosquitoes from all points of view. The present volume includes the adult and pupal characters of the African Culicines, together with the late author's judgment about the affinities of this difficult group. It may readily be understood that it has not been easy to secure coherence between the first and third volumes, which divide the account of the Culicines, and have come out at a five-year interval : none the less they are not seriously discrepant.

The greater part of the present book is descriptive and systematic : it deals with some 290 species of Culicine mosquitoes. The descriptions have been freshly drawn up for the present book, which also contains keys and lists of localities. It is illustrated by many hundred line drawings.

It is sometimes thought that a systematic work must be so specialized as to appear dull to the ordinary reader, but there are a number of points of very general interest in the volume before us. Owing to the need to recognize early stages in the field (in order to control mosquito breeding in the particular spots where harmful species breed) much attention has been given to the larvæ of these insects : indeed one might say that there are few groups of insects in which the early stages of so large a proportion have been collected, figured and considered. We have therefore what is still unusual, a systematic work which takes into account the early stages as well as the adult. The late Dr. Edwards had an encyclopædic knowledge of everything pertaining to these insects and could certainly use larval and pupal characters with as much mastery as he could those of the adult. It is therefore interesting to observe that, in his opinion, precedence should be given to the characters shown by adults, in those cases where there appears to be a conflict between the evidence derived from the adults and from the early stages.

The very close study to which African mosquitoes have been subjected has revealed information of general interest about the characters which sometimes separate species. There are, for example, several little groups in which there are sharp characters in the male genitalia, but no others, either in the external anatomy of the mosquitoes themselves or of their larvæ : but one is not entitled, from this, to conclude that specific differences will invariably be found in the genitalia,

for in other groups there are 'good species' with evident differences in pattern and colour but no points of distinction in the genitalia. There are also several instances of insects which are more readily distinguished in the immature stages than in the adult.

The book includes an excellent, well-illustrated introduction to the external anatomy of Culicine mosquitoes (adults and pupæ) with special reference to the characters used in systematics. This part of the book has considerable general value.

Dr. Edwards has given a large amount of space to discussing the zoogeography of his subject, and the provinces and subprovinces which may be based on these considerations. On the whole, he is able to accept the regions already proposed by Chapin for African birds.

The volume is a very scholarly addition to knowledge. In this, which was perhaps his last major work, the late Dr. Edwards has left something which will be of value not only in Africa but also in all other parts of the world. P. A. Buxton.

RECENT ADVANCES IN PHYSICS

Reports on Progress in Physics
Vol. 7 (1940). General Editor: J. H. Awbery. Pp. iii+362. (London: Physical Society, 1941.) 22*s*. 6*d*. net.

In spite of 'blitzes' and 'black-outs', of paper shortages and general war tension, vol. 7 of the Physical Society's "Reports on Progress in Physics" for the year 1940 has duly made its appearance, as well printed, well produced and not notably slimmer than usual. Physicists have come to rely on these annual volumes to keep themselves alive to developments in parts of their vast subject not peculiarly their own pet province, and the Society may be congratulated on the courage and foresight which have enabled it to continue the series through at least the first two years of the greatest war in history.

What hair-breadth escapes the volume may have suffered during production, and what may have been the editorial difficulties we are left to guess. The editor offers no apologies, for none are needed; and if he feels, as well he may, a quiet glow of satisfaction at a job well done under trying conditions, he allows no sign to escape him. Only here and there a modest footnote indicates that the times have not been quite normal. Future generations of readers—for these volumes are of more than ephemeral interest—will no doubt learn with surprise that "Dr. Eirich was engaged on this article when he was interned, and it has therefore been necessary to print it without bibliographical references". For the rest, the substitution of one author for another in one of the articles, and the inability of two others to follow up their very interesting article on the "Electrical Discharges in Gases" with a second part dealing with the practical applications of the subject are the only other *contretemps* recorded.

One of the anticipated joys of skimming through the latest volume of "Progress Reports" is the realization of how many branches of physics there are of which one knows next to nothing; and further, how many others, which one thought to have been worked out and safely interred in the pages of some standard text-book, have suddenly taken on a new lease of life. Dr. E. G. Richardson has collected more than ninety references to papers on sound published within the last two years (we wish he could have worked them into a rather more connected story) and Dr. Beattie and Dr. Stockmeyer, of the Massachusetts Institute of Technology, have found something fresh to say on the subject of "Equations of State". "Infra-red spectra," one knows, is a serial story which is likely to run through many volumes, but Dr. Harald Nielson's instalment in the present volume (again a contribution from the United States) is very welcome. One might have thought, however, that "Surface Tension" had been definitely cleared up. Dr. R. C. Brown in his article on the subject convinces us to the contrary.

What is generally known as "Modern Physics" is, of course, represented, though the editor, as usual, has wisely confined it within reasonable bounds. Dr. Feather writes on "The Gamma Radiations emitted in Nuclear Processes" and Dr. Peierls contributes an excellent article on "The Bohr Theory of Nuclear Reactions". Though it may seem a little invidious to distinguish a particular author when all are so good, one must say that Dr. Peierls's article is a model of the way in which such things should be done. With a minimum of mathematical symbols he succeeds in conveying to the average physicist, who has neither the time nor (to be quite frank) the mathematical ability to follow the original papers, a clear picture of the physical principles involved in the argument, and in convincing him of their plausibility.

Astronomy is represented by articles on solar physics, by Dr. Thackeray, and on the absorption of light in interstellar space, by Dr. Hunter. Dr.

Roberts gives an interesting account of interactions of gases with metals and crystals. Technical physics provides material for articles on photo-electric photometry, electron microscopes and new lenses ; and, in different vein, Dr. Allan Ferguson provides a charming little postscript on the development of the teaching of experimental physics in British universities.

It is an interesting and well-chosen menu which the editor has provided for his readers this year, and, on the whole, it is admirably served up. The authors have kept in mind the fact that, however much we may deplore it, the average physicist professionally engaged in cultivating his own little section of the field is no longer an expert in other parts of the subject, and looks to "Progress Reports" to keep him *au fait* with developments there. He will not be disappointed with the present volume. In the dark days through which we are passing, though money is being lavished on research on a scale unthinkable in the days when physicists were merely engaged on the advancement of learning and the betterment of mankind, it is unlikely that the results of their work will be available for publication in the near future; though we may hope that something of permanent value in science will result from so much strenuous activity. World war must call a halt to progress in physics, as to so many other civilized activities. We trust, however, that the ingenious editor will still be able to find some progress to report, and that he will find ways and means of reporting it.

J. A. CROWTHER.

ZOOLOGICAL LITERATURE

The Zoological Record

Vol. 76 : Being Records of Zoological Literature relating chiefly to the Year 1939. Compiled for the Zoological Society of London by A. G. Brighton, M. Burton, A. B. Hastings, C. A. Hoare, W. Nicoll, A. E. Salisbury, J. K. S. St. Joseph, W. L. Sclater. M. A. Smith, C. J. Stubblefield, E. Trewavas, E. I. White, R. J. Whittick, and the Imperial Institute of Entomology. Edited by Malcolm A. Smith. Pp. 1420. (London : Zoological Society of London, 1940.) £3 ; also in 19 Sections, issued separately.

THE seventy-sixth volume of the "Zoological Record", dealing with the literature published in 1939, appears a good deal later than usual (although some of the sections were issued separately many months ago), which, in the circumstances, is less surprising than that it should appear at all. Its compilation under war conditions must have involved much additional labour and great determination on the part of the editor and his contributors, and they are to be warmly congratulated on the completion of their task.

The arrangements for the cataloguing and indexing of scientific literature are among the problems of reconstruction that will have to be considered when the scientific world can again turn its attention to such things. It may not be inopportune, therefore, to inquire how far the "Record" meets the needs of present-day zoologists, and whether any improvements can be suggested to meet the needs of the future, so far as these can now be foreseen.

The "Zoological Record" is, by a long way, the senior of the current bibliographies that serve the congeries of sciences grouped under the name 'zoology'. To have maintained a continuous existence for more than three-quarters of a century is sufficient evidence of usefulness. Nevertheless, it is matter of common knowledge that its financial position is far from secure. For many years the Zoological Society itself sustained the very heavy loss involved in the publication of each annual volume. Some fifteen years ago, in response to an appeal sent out by Sir Sidney Harmer, a number of scientific societies and institutions in Great Britain and the United States and a few generous individuals came to the help of the Society, and enabled the "Record" to be carried on. A financial statement prefixed to the present volume shows that this help continues. In the year 1939, £450 was contributed by the trustees of the British Museum, £250 by the Zoological Society, and smaller sums amounting to £172 came from other sources. These contributions, however, failed by £114 to bridge the gap between the cost of production and the amount received from subscriptions and sales. Clearly, an increased circulation must be aimed at if the "Record" is to have an assured future.

The "Zoological Record" was originally founded by systematists for systematists, and the arrangement of its subject-matter has always been predominantly systematic. It will be generally agreed that in this respect it has been, on the whole, remarkably successful. It is still the only publication to which the zoologist can turn with the

certainty of finding (within the limits of human fallibility) references to all new genera and species, and all important additions to the systematic knowledge of species already named and described. There can be very few serious workers in any branch of descriptive zoology, in any part of the world, who find it possible to carry on without at least occasional reference to its pages. There are, indeed, some minor blemishes and a few major ones apparent in the present volume that might be remedied without increasing its bulk, but there is no need to dwell on them here.

But if the "Systematic Index" sections of the "Record" do meet, more or less adequately, the needs of systematists, other zoologists are likely to find themselves bewildered if they look for guidance to the "Subject Index". In this index a uniform classification of the subject-matter in each of the divisions of the "Record" allotted to the major groups of the animal kingdom is obviously desirable. Yet in the present volume no such uniformity exists. Each recorder makes his own choice of categories under which the data are classified and the headings used for them. This haphazard arrangement of the Subject Index makes it of little use to zoologists engaged in branches of research other than systematics.

W. T. Calman.

THE SCIENCE OF CANNING

Canning Practice and Control
By Osman Jones and T. W. Jones. Second edition, revised and enlarged. Pp. xiv+311+107 plates. (London: Chapman and Hall, Ltd., 1941.) 32s. net.

That a second edition of this book has been found necessary in such a short time proves that it has fulfilled a definite purpose. There are not many authoritative books on canning—a section of the food industry which, although not new (for certain of Napoleon's armies were supplied with canned foods), has nevertheless only developed to its present huge proportions during the last forty years or so—and therefore a compilation by the two authors, both of whom have had considerable (practical and theoretical) experience, was received with pleasure by those interested in the application of science to the industry. There are many new features in the second edition, but one might have expected that certain aspects of the first edition would have been altered—as they could have been with profit to the book. The difficulty, as the reviewer sees it, was to do justice in some three hundred pages to the whole of the ground which the authors attempted to cover; a difficulty which has been experienced by many authors seeking to stress the scientific aspect of an industry whilst endeavouring to convey to the reader an appreciation of the 'practice' of the industry.

What, in effect, have the authors attempted to achieve? They have endeavoured to bring before their readers a practical treatise on canning and an authoritative text-book on the chemistry and bacteriology of canning, and, in the reviewer's opinion have only succeeded in drawing together from a scattered technical literature and from purely scientific papers, certainly reinforced by their own practical experience, a number of facts which are largely commonplace. If the experienced packer were faced by some out-of-the-ordinary problem, reference to this book would scarcely yield an answer. The whole trouble is that limitation of space results in a superficial treatment of the subject. The best practical chapter is that concerned with packing in glass, for the information on this aspect of 'canning' is notably meagre.

The same restriction has reduced the value of the scientific sections of the volume. The reader would naturally expect authoritative statements on tests to be carried out on the products being canned. The authors have chosen to detail, as an example, some thirty-five different methods of analysis in approximately twenty pages, with the obvious result that the instructions are sometimes incomplete, sometimes ambiguous and sometimes carelessly presented.

The bacteriological sections also suffer. The authors have considered it advisable to treat with some of the fundamentals of bacteriology, but they have also practical hints to give, methods of testing to describe, with the result that both theory and practice suffer. The chapter on the staining of micro-organisms is a good one and full of useful information.

Unfortunately the book reminds the reviewer of publications where the work of the authors has been marred by a too ambitious interpretation of their object.

This is the opinion of the reviewer, but he may be the only person in step in the battalion—a second edition has been found necessary.

L. H. Lampitt.

LOWLAND TROPICAL PODSOLS AND THEIR VEGETATION

By DR. P. W. RICHARDS,
BOTANY SCHOOL, CAMBRIDGE

PODSOLS are soils characteristic of cool temperate regions with a damp climate, and until recently they were generally thought to be absent in the zone between about 40° N. and 40° S. Some years ago, however, Senstius[1] showed that podsolization occurred at high altitudes in the mountains of Java and the Philippines, though he did not find any mature podsols. Hardon[2] afterwards described well-developed podsols at about 2,000 m. in the Arfak Mountains in New Guinea (latitude 1° 10′ S.). In these observations there was nothing surprising, because, except for the smaller seasonal range of temperature, the climate at high altitudes in the equatorial zone may be very like that of cool temperate lowlands. It is the object of this article to point out that podsols (or soils similar to podsols in most of their characteristics) occur in the tropical lowlands down to sea-level, a fact which is not generally recognized and which does not accord with the climatic theory of soil development—at least in the form in which it is often stated.

These podsols of the tropical lowlands are not found sporadically, but have a wide distribution in the tropical rain-forest region of both hemispheres. They occur side by side with tropical red earths, the prevailing soil type of the equatorial zone, and are developed under the same climate. Where the rainfall permits, the natural climax vegetation of both tropical red earths and of lowland tropical podsols is usually rain-forest; but the rain-forest of the podsols has marked characteristics of its own and may be regarded as an edaphic climax. Under certain conditions (not yet understood) the podsols of the rain-forest belt may bear locally a type of evergreen scrub which is apparently also a climax type of vegetation.

These facts have been established by a series of steps which have been more or less as follows. The existence of bleached sands ('white sand') in the Tropics has been known for a long time. The botanical traveller Richard Spruce[3] met with large areas of white sand in the Rio Negro region of the Amazon and noted that the rain-forest on this soil—called by the natives *caatinga* forest—was different in composition from the forest elsewhere. The 'bleached earths' of the tropics are mentioned by Ramann, who in his "Evolution and Classification of Soils"[4] refers to the fact, well known to travellers in the South American jungle, that streams rising in the bleached soils are coloured brown by highly dispersed humus ('blackwater'), while streams from the red earth soils are colourless ('whitewater').

Bleached sands are widely distributed in the Guiana peneplain. At Moraballi Creek in the Essequibo basin, for example, a deep, porous and completely bleached sand forms a capping to low ridges and plateaux. This sand bears a highly characteristic type of rain-forest, dominated by the leguminous tree, *Eperua falcata* Aubl. (Soft Wallaba). This 'wallaba forest' is strictly confined to the bleached sand, and where it adjoins other soils the vegetation changes abruptly. In some parts of British Guiana the bleached sand bears other peculiar types of rain-forest which replace 'wallaba forest'. In 1934 a few analytical data from a soil profile in the 'wallaba forest' were published[5]. The significance of the data was not fully appreciated at the time, but it was noted as remarkable that the samples, though acid (pH about 4·8), gave a negative result with Comber's test, showing that they were deficient in iron as well as in bases (as would indeed be expected from their appearance).

In the Malayan region, bleached sands, similar to those of South America, were seen by Beccari[6] and probably by other travellers, but they seem largely to have escaped the notice of soil scientists and botanists. In 1932 I met with bleached sands in several localities in Sarawak (Borneo)[7], for example near sea-level at Marudi on the Baram River and at an altitude of about 750 m. on Mount Dulit. These sands were very similar to the 'white sand' of British Guiana, except that the texture was somewhat coarser. The vegetation was a type of evergreen rain-forest without a single dominant species, but strikingly different from the typical mixed dipterocarp forest which is the climatic climax of the region. This type of forest had previously been described from South Borneo by Winkler[8], who had called it *Heidewald* or 'heath forest'. The 'heath forest' of Marudi and Mount Dulit strikingly resembled the Guiana 'wallaba forest', in structure and physiognomy, though there was of course no species common to the two. Very significantly the Sarawak 'heath forest' differed from the local type of mixed rain-forest in precisely those characteristics in which the Guiana

'wallaba forest' differed from the Guiana mixed forest. The common factor between the two must clearly be a similarity of soil as well as climate.

Several soil profiles were examined in the bleached sand of the Sarawak 'heath forest'. The analyses showed the same feature which characterized the 'wallaba forest' soils—all the samples gave a negative or feeble reaction with Comber's test, though all of them were acid. In a brief discussion of these data I pointed out that the 'heath forest' soil strongly resembled a European podsol; unfortunately the analyses were not carried far enough to establish this conclusively.

The fact that the bleached sands of the Malayan lowlands are actually podsols was finally demonstrated by Hardon[9] in a paper published in 1937. In this, soil profiles were described from the island of Bangka and from a locality in East Borneo: the vegetation in both places was *padang*, a type of heath-like scrub or poor woodland, which occurs in areas with a rain-forest climate, and which is ecologically and floristically related to 'heath forest'. Both types of vegetation are found on bleached sands, and transitions from one to the other have been recorded. Some of Hardon's data are given in the accompanying table.

PROFILES OF LOWLAND TROPICAL PODSOLS.
After Hardon (1937).

Locality	Horizon	Depth cm.	Description	Percentage of sand (0·05–2mm.)	Percentage of clay (0·0005–0·005 mm.)	Organic Matter (%)	Molecular ratio $\frac{SiO_2}{Al_2O_3+Fe_2O_3}$ (for clay fraction)	*p*H	CaO (%)
Padang Loewai, E. Borneo	A_0	0–20	Brownish-black half-decomposed organic material	—	—	—	—	2·8	—
	A_2	10–120	Loose white quartz sand	97·3	0·5	0·1	—	6·1	0·008
	B	120–170	Yellowish-brown quartz sand	93·9	2·8	1·2	—	5·4	0·002
Bangka	A_0	0–10	Half-decomposed black organic material mixed with coarse sand	—	—	—	3·62	2·7	—
	A_1	10–25	Loose greyish-black hulme quartz sand	95·6	1·6	—	7·17	3·9	0·022
	A_2	25–40	Loose greyish-white quartz sand	94·0	0·6	—	8·64	6·1	0·032
	B_1	40–70	Hard pan. Dark brown, very compact quartz sand	86·9	7·2	5·2	0·42	3·9	0·029
	B_2	70–100	Loose light brown quartz sand	92·1	4·6	—	0·31	4·6	0·035

Both Hardon's profiles have a surface layer of blackish humus followed by a typical bleached horizon. Below this is a coloured horizon, which in the Bangka profile takes the form of a hard pan: clearly this is a *B* horizon. The percentage of clay is less than 1 per cent in the bleached layer and even in the coloured layer it is less than 10 per cent. The silica/sesquioxide ratios are typical for podsols—high in the *A* horizon, low in the *B*—indicating that sesquioxides are being removed from the *A* and deposited in the *B* horizon, while silica remains behind. All horizons are extremely poor in bases, even compared with other tropical soils. A striking feature is the excessively high carbon/nitrogen ratio of the humus layer (in one sample as high as 57), indicating very incomplete humification. The humus of these soils would thus appear to be of a *mor* rather than of a *mull* character.

There can be little doubt that Hardon is right in considering these soils to be podsols. Though in the Sarawak profiles no *B* horizon was found, probably because the sample pits were not deep enough, it seems certain that they belong to the same soil type. Hackenberg's[10] account of the South Bornean 'heath forest' mentions a blackened, consolidated soil layer at a depth of 1·5 m., which is doubtless the *B* horizon. That the South American bleached sands are also to be regarded as podsols seems extremely probable, though a full series of analyses for a deep profile is still needed. A profile at Moraballi Creek showed pure white sand extending down to 6 ft.; possibly a *B* horizon would have been found at a still greater depth. Unpublished notes by Mr. T. A. W. Davis on a white sand profile at another locality in British Guiana indicate a yellow layer at 77 in., which is possibly the *B* horizon.

The occurrence in the tropical lowlands of what appear to be podsols raises some interesting pedological questions. Under a tropical rain-forest climate, owing to the excess of precipitation over evaporation, movement of the water in the soil is predominantly downwards. Owing to the constantly high temperature, which accelerates the activities of micro-organisms, humus usually does

not accumulate. Now at high temperatures in water containing little organic matter, silica is relatively soluble and the sesquioxides of iron and aluminium relatively insoluble; thus silica tends to be removed preferentially from the upper soil horizons and sesquioxides to remain behind. The chief soil-forming process in the tropical rain-forest region is thus normally laterization, resulting in the development of a tropical red earth. The opposite process to laterization is podsolization, which is the removal of sesquioxides from the upper horizons, leaving silica behind. This usually takes place at temperatures low enough to favour humus accumulation, because in water containing dissolved organic matter sesquioxides are more soluble than silica.

Now the *padang* and 'heath forest' soils of the Malay islands and the white sands of British Guiana occur in what is a typical rain-forest climate both in respect of temperature and of rainfall. Indeed these soils are found side by side with typical red earths bearing normal mixed rain-forest. Why should podsolization sometimes take place instead of laterization ? Hardon gives no complete answer, nor can one be offered here; but it is at least clear that the nature of the soil-forming process must be ultimately determined by the properties of the parent rock. The bleached sands of Borneo are derived from coarse-grained Miocene sandstones which are probably initially poor in bases and in materials which would readily weather to a clay fraction. The Guiana podsols probably arise directly from white sands ultimately derived from the breakdown of granite, but afterwards sorted and deposited in a shallow sea during the Tertiary. Here again the parent material was probably deficient in bases and clay-forming materials from the beginning. In these extremely base-deficient soils there seems to be a tendency for raw humus to accumulate, even under tropical conditions. This raw humus leads to the preferential removal of sesquioxides rather than silica. Thus the nature of the parent rock locally outweighs the effects of climate and deflects the course of soil development from the start. If this is so, it strikingly confirms the view that vegetation, animals, soil and climate are all parts of one very complex interacting system (the "ecosystem" of Tansley): to regard one component of this system as determined by any other single component has little meaning.

Though all the factors controlling their development are not yet clear, it may be accepted that podsols occur in the tropical lowlands. These *lowland tropical podsols*, as they may be called, to distinguish them from the podsols of tropical mountains and temperate regions, have a wide distribution in both hemispheres. As well as occurring in Asia and America, there are indications, though no definite evidence, that they are found in tropical Africa. They are derived from sands or sandstones poor in bases, and bear a vegetation markedly different from the mixed rain-forest of the tropical red earths, which is the climatic climax of the region. In Borneo, in habitats with unimpeded drainage, the natural vegetation of the podsols is either 'heath forest' (perhaps better termed 'primary lowland rain-forest of bleached sands') or *padang* (evergreen scrub). The factors determining the latter are not climatic; if not due to felling, burning or some other biotic factor—as seems to be the case—it must depend on some soil factor, possibly a high degree of podsolization. In swampy habitats on soils of the podsol type, wood-moors (*Waldmoore*) develop. These are extensive lens-shaped masses of peat bearing a peculiar forest vegetation. They are found in the low-lying coastal plains of Borneo and Sumatra, and as shown by Polak[11], are closely comparable with the raised bogs of temperate regions, though the peat is formed chiefly of wood, not of the remains of herbaceous plants. In ordinary tropical swamps there is little tendency to accumulate raw humus; the peat-formation in these wood-moors cannot be due only to water-logging and consequent poor aeration. Possibly the very low concentration of bases in the ground-water inhibits the activities of micro-organisms.

In South America there are analogues to 'heath forest', *padang* and wood-moors. The 'wallaba forest' of Guiana, and other types of white sand forest, are the counterparts of the Bornean 'heath forest'. A corresponding type to *padang* in South America is the so-called '*muri* bush' of British Guiana, a low evergreen scrub dominated by *Houmiri floribunda* Mart. This occurs on white sand, chiefly as islands in 'wallaba forest'. Finally there are the 'pegass swamps' of the Guiana coastal plain, which though little investigated, are certainly very similar to the Malayan wood-moors.

The main reason why tropical podsols have been neglected is no doubt their low agricultural value. Attempts at farming on the white sands of Guiana show that they are unsuited to any kind of permanent cultivation (see Milne[12]).

TWO THOUSAND YEARS OF HOME LIFE IN NORTHERN SCOTLAND*

By Dr. A. O. Curle, C.V.O.

At the extreme southern end of the mainland of Shetland there towers up the massive headland of Sumburgh Ness. Sheltered behind the Ness, and flanked by a long promontory which springs from the mainland on the west, is the Sumburgh Voe, a peaceful stretch of water running inland for about a mile. From the west side of the Voe, a low grassy headland rises above the general level of the coastline, affording a site for the various buildings which, now in ruins, bear the name of Jarlshof.

Some forty years ago, a violent storm swept the sand from the front of the shore bank on the side of the Sumburgh Voe and exposed some buildings. Here, adjacent, more extensive excavation in recent years has brought to light a group of dwellings, dating from the pre-Bronze Age of Shetland down to the Viking period in the eleventh–twelfth century.

The first dwelling to be described belonged to a pre-metal period in Shetland, for not a trace of metal or of any metallurgical process was found within it. It was a house built of drystone with flat-sided boulders selected from the adjacent beach, the walls of which still stood to a height of 2–3 ft. On plan it was elliptical, with the entrance in the centre of one end, and consisted of a small central courtyard, measuring some 10 ft. in diameter, with, on one side, two small cells rounded at the back, and, on the other side, two less deeply formed recesses, with a long chamber placed transversely at the back and measuring some 10 ft. by 6 ft. 6 in. There was ample evidence that the house was arranged to accommodate the cows as well as the family. Beside one of the lateral chambers lay the quernstone, *in situ*, a long trough-like contrivance, open at one end, on which the inhabitants had ground their grain, with the rubbing-stone lying nearby. Against the inner side of the front wall of the house lay four small four-sided pots of steatite or soapstone, evidently drinking-vessels, three of them as fresh as on the day on which they had left the maker's hand, and the fourth, a bottomless specimen which, inverted, had been used for the support of one of the others. The house must have been hurriedly vacated, and the drifting sand had dropped its mantle over everything before any marauder had come to disturb the contents. Sherds of pot represented the food vessels and cooking-pots. At a height of about 2 ft. above floor-level there projected from the side wall, opposite to where the quern lay, a small vertebra of a whale, placed in such a way that the side of the canal down which passed the spinal column protruded from the wall-face, thus providing a loop to which a cow or a calf could have been tethered.

Numerous relics were found in the dwelling, including a number of rude stone tools, among them objects of slate fashioned with serrated or sharp cutting edges, probably used in the preparation of skins, and closely resembling relics found in Norway belonging to the Arctic culture, and referable to a post-Magdalenian period. As neither whorls for spinning nor combs to be used in weaving were found we may presume that clothing was entirely formed of hides, carefully prepared with the help of the many slate and bone objects found in the course of the excavation. The pottery was rudely fashioned by hand, and without ornamentation, and the cooking for which it was used was effected by sinking the pot in the peat fire up to the shoulder. From the encrustation on the inner face of the potsherds, the diet appeared to have consisted largely ot stews.

From the entrance to this house a stone-paved passage of secondary construction, led by a rude stair of two or three steps, to a corridor. At the end of this corridor, on the right, a doorway opened into a small chamber. Here was a vivid picture of the life that had been lived within. At the entrance lay a quern, and, set up against it, ready to hand, was the rubbing stone to be used upon it. There was no trace of grain near it, so, presumably, the quern had been used for working up the clay which was found nearby, as a film of that substance was found on the surface of more than one of these querns in the course of the excavations, indicating that the grinding of grain was not the only purpose for which they were used. On the opposite side of the doorway from that on which lay the quern, was a heap of clay, carefully levigated, and still in a perfectly plastic condition suitable for making pots. Behind the quern were the remains of the fire on which the pots were, no doubt, fired; while in the wall behind the quern was a small ambry.

A doorway on the other side of the passage gave access to another house.

* Substance of a lecture entitled "Glimpses of 2,000 Years of Home Life as revealed by Excavations in the North of Scotland" delivered at the Royal Institution on May 15.

The plan of the courtyard house is as ancient as the time of the Minoan culture of Crete[1], reckoned to have belonged to a period between the second and third millennium B.C., and, as there is an absence among the relics from Jarlshof associated with the houses of this type, which would connect its introduction with any folk immigration, it may well have been traditional there from the advent of the Neolithic inhabitants to the island.

To the right of the entrance, on coming into the house, was a cell somewhat smaller than the rest. The front had been purposely blocked by large stones laid across it, and the cell itself had been converted into a rubbish pit in which were found some remarkable relics. Among them were numerous fragments of clay moulds which had been used for casting bronze swords ; pieces of more than one mould for casting a bronze axe ; a piece of the matrix of a mould for a pin of the sunflower type ; and several other fragments of moulds for indeterminate objects.

Clay moulds of the Bronze Age are exceedingly rare in Great Britain, and, not many years previous to this, the first recognized fragment of a sword-mould had been found on Traprain Law, near Haddington. It had previously been doubted, moreover, whether bronze had ever reached Shetland, and the appearance of a bronze sword on the island, far less the existence of a factory of them, had never been dreamed of.

On a secondary hearth was found a number of grains of bear, a species of coarse barley, showing that the inhabitants had been cultivators of the soil, as the numerous bones of sheep and oxen in their middens and elsewhere showed that they had owned flocks and herds. The complete absence of fish bones, as well as of fish hooks and spears, seemed to indicate that they did not seek their living on the sea, though the masses of limpet shells in the middens, and, to a lesser extent on the floors of the dwellings, showed that shell-fish formed one of their main sources of food.

On the paving of the court there was visible the site of the fire on which the smith had smelted his bronze. But a more interesting discovery was to follow. On clearing the floor nearby there was found a small pit in the vicinity of the hearth, measuring across the surface some 16 in. by 9 in., and in depth 11 in., with the sides converging until they were 6 in. apart, obviously the casting-pit into which the moulds had been thrust preparatory to the reception of the molten bronze.

But, besides the technical interest in these moulds and the casting, there is an even greater interest in the evidence they afford of a fresh contact with the outer world which Shetland had acquired.

The advent of the sword-smith did not synchronize with any apparent change in the character of the inhabitants of the Jarlshof settlement. Their houses continued, during the occupation in which the moulds were found, to be of the primitive courtyard type, and their tools and implements were little, if at all, affected. True, they had acquired new and formidable weapons of war, presuming the axe to be also a weapon, for, except for use on driftwood, bronze tools could here only be of limited application, the islands being treeless. Accordingly, the moulds supply no evidence for the advent of a fresh influx of people but rather of the coming of a single sword-smith, perhaps with his family, from across the ocean, bringing with him the implements of his craft. The type of the leaf-shaped sword, the sunflower pin, and other products, show that, from whatever land he had sailed, he had been trained in the Britannico-Irish traditions[2]. As Orkney, owing to the general difference of its archæological culture, may be ruled out as the land of his origin, we must look even farther afield, to the Western Isles, or even to Ireland itself, for the source from which he ventured on the perilous seas, in what would seem to us a very inadequate vessel for so long a voyage.

Besides the moulds, relics very similar to those found in the house previously described were recovered here ; but also chisel-shaped objects of bone, having the socket at one end, a type which corresponds closely with one from Denmark dating from a very remote antiquity. The presence of the Danish *Maglemös* type of chisel and of the peculiar slate tools suggests that Shetland had, perhaps for centuries, remained practically unknown to the outside world, lost in the wastes of ocean, and still preserving cultural evidence of a remote contact with northern Europe.

Adjacent to this house, but not in direct communication with it, was another and larger dwelling, which had been constructed on the ruins of a still earlier building. It also was a courtyard house. Here, too, the sword-smith had left evidence of his work, for numerous fragments of clay moulds were scattered about. In all, it was reckoned that as many as thirty swords were represented by the numerous fragments found in the settlement.

Until a few years ago, although the Viking occupation of parts of the north of Scotland and of the northern and western isles had left an indelible record in the place-names as well as in the surnames and physical characteristics of the people, yet no trace of the remains of a Viking dwelling had ever been exposed, or such a discovery recorded. By good fortune, such a house, and an associated homestead, were found at Jarlshof, which led afterwards to the discovery of another at Freswick on the Caithness coast, some five miles south of John o' Groats.

The earliest Viking houses were oblong on plan, with rounded ends. The walls were about 1½ m. thick and the same in height, and on the top of them rested the edge of the roof of timber and turf, supported by a row of wooden posts along each side of the interior. The ordinary rooms were three in number: the dining- and living-room known as the *stofa*; the sleeping-room or *skali*; the kitchen or *eldhus*. The Shetland example was a typical long house measuring, in its original state, 95 ft. in length by 12 ft. at either end, and 18 ft. at the centre.

At Freshwick a bath house was discovered. It was a small chamber, forming a somewhat irregular square of about 5 ft., with an entrance by a step in one side. The floor was carefully paved, except for a small area, in one corner where the fireplace had been, and which was filled with burnt broken stones and peat ash. From the floor a well-fashioned drain led through the wall of the chamber, and, continuing beneath covers along the floor of the main building, eventually discharged by way of an offset into a sump.

This was a typical vapour-bath, such as had been used in Scandinavian countries since early times, and which may still be met with there in country districts.

OBITUARIES

Dr. R. Bracher

DR. ROSE BRACHER, who died after a short illness on July 15, was born in 1894, the elder daughter of Reuben Bracher, a well-known teacher in Salisbury. She was educated in Salisbury and at the University of Bristol, where she graduated with first-class honours in botany in 1917. A year later she took her M.Sc. and then spent two years as demonstrator in the London School of Medicine for Women. The award of the Rose-Sidgwick fellowship allowed her to spend a year at Wisconsin, after which she returned to London as lecturer at East London College. In 1924 she came to Bristol to undertake research work; in 1926 she became assistant lecturer in the Department of Botany and in 1929 lecturer. In 1940 she was appointed senior lecturer—a title reserved for those who have given distinguished service to the University. A month ago she was elected a member of the Senate.

Dr. Bracher's principal scientific work was a study of the ecology of the great tidal mud-banks of the Bristol Avon and especially of the species of Euglena, which is the most conspicuous feature of its vegetation. Euglena appears on the surface and sinks into the mud with a rhythm which is largely caused by variations in illumination, and Dr. Bracher succeeded in working out in detail the part played by light and other factors in this striking phenomenon. The results were published in three distinguished papers in the *Annals of Botany* (1919), the *Journal of Ecology* (1929) and the *Proceedings of the Linnean Society* (1937). During the last ten years she was constantly engaged, along with her students, in work on the ecology of the Bristol district; the results have appeared in a series of papers of the greatest use to students of the vegetation of Somerset. As another consequence of this work she published two books, "Field Studies in Ecology" and "Ecology in Town and Classroom", which have been of especial use to teachers, showing, as they do, how interesting work can be carried on even in very unfavourable conditions.

Dr. Bracher was an admirable teacher and her services were much in demand for extra-mural work. She had notable success in rousing to an interest in biology members of W.E.A. classes and of others of that kind. In the University she had an unrivalled knowledge of the students, their problems and difficulties, and for some years she had been warden of the Women Home Students' Society. The tragedy of her early death is felt by a wide circle of colleagues and friends.

M. SKENE.

Sir Francis Anderson

THE death is announced of Sir Francis Anderson, emeritus professor of philosophy in the University of Sydney.

Sir Francis, who was eighty-two years of age, must have been almost the last survivor of that remarkable succession of pupils of Edward Caird (professor of moral philosophy in the University of Glasgow during 1866–1894) who themselves attained eminence as professors of philosophy. After an outstanding undergraduate career, crowned in 1893 by the award of first-class honours and the Clark fellowship in mental philosophy, Anderson spent two years as Caird's assistant, two years as assistant minister of the Australian Church in Melbourne, and then started upon his long and fruitful career as a teacher of philosophy in the University of Sydney—first as lecturer, and later, from 1890 until 1922, as professor in the newly founded chair of logic and mental philosophy.

Among the distinctions which marked this period were the presidency of the Mental Science Section of the Australasian Society for the Advancement of Science in 1897, and the presidency of the Social Science Section in 1907. Retirement from academic duties brought no abatement in his philo-

sophic interests, and from 1923 until 1927 he acted as editor of the *Australasian Journal of Psychology and Philosophy*. In 1927 his Alma Mater recognized his notable services to learning by conferring upon him the degree of doctor of laws. In his later years the cause of the League of Nations claimed much of his time and energy, and he was, from 1931 until 1936, president of the League of Nations Union (New South Wales). In 1936 he was created a knight.

Sir Francis's contribution to the literature of his subject was chiefly in the form of papers; but although he produced no major philosophical work, his influence upon the development of philosophical studies in the land of his adoption was powerful and widespread. The sphere of his academic influence and interests, however, extended far beyond the narrowly philosophical. The social sciences in general found in him an enthusiastic and untiring champion. Indeed the successive establishment in the University of Sydney of chairs in education (1910), economics (1912) and psychology (1920) was in no small measure due to his energetic advocacy. C. A. CAMPBELL.

WE regret to announce the following deaths:

Dr. C. S. Fisher, acting director of the American School of Oriental Research in Jerusalem, on July 20, aged sixty-five.

Prof. O. L. Shinn, professor of applied chemistry in the University of Pennsylvania, on June 10, aged sixty-nine.

Dr. L. A. Strong, chief of the U.S. Bureau of Entomology and Plant Quarantine, on June 2, aged fifty-four.

NEWS AND VIEWS

Sir Prafulla Chandra Rây, C.I.E.

ON August 7 the distinguished Indian chemist, Sir P. C. Rây, will celebrate his eightieth birthday. As a young student, Sir Prafulla was fortunate in coming under the influence of the late Sir Alexander Pedler, then professor of chemistry at the Presidency College, Calcutta, and on his recommendation Sir Prafulla proceeded to work under the late Prof. Crum Brown at Edinburgh, where in due course he graduated with the degree of D.Sc. Returning to India he became professor of chemistry at the Presidency College, Calcutta, and he remained in this post until his retirement under the age limit in 1916. He was then appointed Palit professor of chemistry at the University College of Science, retiring owing to failing eyesight in 1937. Valuable as have been Sir Prafulla's personal investigations, mainly in the field of nitrite chemistry, his outstanding contribution has been the foundation of an Indian school of chemistry. A true 'guru', devoting much of his income to the support of poor students, he sent forth from his laboratories a constant stream of young chemists fired with a zeal for original research. These young chemists now occupy most of the chairs of chemistry in Indian universities.

Sir Prafulla's interests have not been confined solely to academic research; his historical sense is shown in his "History of Hindu Chemistry", and he was responsible also for the foundation of the Bengal Chemical and Pharmaceutical Works. Naturally, Sir Prafulla's important work for India has received general recognition. He was appointed C.I.E. in 1912 and was knighted in 1916. He is a fellow of the Royal Asiatic Society of Bengal and of other Indian academies, and an honorary graduate of the Universities of Durham and Calcutta. He was president of the Indian Science Congress in 1920 and the first president of the Indian Chemical Society (1924). We trust that he may long be spared to inspire Indian youth.

Great Britain and the U.S.S.R.

IN NATURE of July 19, p. 79, brief reference was made to a broadcast from Moscow by Prof. P. Kapitza, which was addressed particularly to scientific workers in Great Britain. Prof. Vladimir Vernadsky, a veteran mineralogist and member of the Academy of Sciences of the U.S.S.R., also broadcast a message. These friendly gestures brought a reply from Prof. A. V. Hill, one of the secretaries of the Royal Society, who broadcast greetings to Russian colleagues and a reply to Prof. Kapitza in the European News sent out by the B.B.C. at midnight on July 14. Since then the Royal Society has dispatched the following cable: "President and Council of Royal Society London send greetings of Royal Society to National Academy of Sciences of U.S.S.R. Moscow. Our countries stand firm as partners in struggle against wanton aggression and our united efforts will ensure that the future of science is not endangered by destruction of those freedoms in which has thrived the work of the great scientists of both our countries enshrined in records of past and achievements of present. In the struggle science has already made and will continue to make essential contributions to victory."

Other bodies and individuals have joined in expressing their satisfaction that the U.S.S.R. can now be numbered among the Allies fighting against Nazi domination. The committee of the Division for the Social and International Relations of Science of the British Association has sent to the Academy of Sciences at Moscow a cable welcoming the alliance of British and Russian science, and expressing the hope that they "may in the near future be united in application to the establishment of a new and happier ordering of the affairs of mankind". The Cambridge branch of the Society for Cultural Relations with the U.S.S.R. sent a cable signed by the vice-chancellor and other members of the University

of Cambridge to the Academy of Sciences, to which Eugene Chudakov, vice-president of the Academy, has replied; and a group of biochemists at Cambridge, headed by Sir Frederick Gowland Hopkins and Dr. Joseph Needham, have sent "greetings and assurances of utmost support" to Russian biochemists through Profs. Bach and Engelhardt, of the Academy of Sciences, and the latter has replied, expressing his conviction that "the cause of progressive humanity will triumph over Hitlerism". Prof. Kapitza and Prof. P. A. M. Dirac, Lucasian professor of mathematics in the University of Cambridge, have also exchanged cables of greeting affirming their belief in victory for freedom of scientific thought.

"Fantasia"

The new film, "Fantasia", shortly to be generally released, will appeal not only to lovers of music, but also, from several points of view, especially to men of science. The basic theme of the film is the interpretation by artists of several well-chosen musical works. The fact that artists were chosen to interpret the music is a new departure for the screen; but of equal interest are the evidences of new technique adopted. The stereoscopic effect produced at the beginning of each half of the programme gives an almost complete impression of reality—in fact, for a moment it seemsal most impossible not to believe that the Philadelphia Philharmonic Orchestra and its conductor, Stokowski, are on the stage of the cinema. The first presentation—one of Bach's toccatas and fugues, so difficult to interpret as anything other than pure music that even the composer could not find a name for it—is here interpreted in a series of colour and wave forms that should delight and intrigue the physicist. He, too, will be amused by the introduction to the audience of the sound track as a "screen personality". Coyly comes the sound track on the screen where he is induced to demonstrate how he reacts to the sounds of various wind and string instruments. Though his reactions are impressionist to a degree, they are obviously based on the actual scientific facts.

Tschaikovsky's "Casse-noisette" is interpreted in a beautifully coloured floral ballet of a type familiar to regular cinema-goers; but susceptible lovers of Beethoven might be irritated by the interpretation of his "Pastoral" symphony-life on Mount Olympus. It is said that Beethoven claimed to compose always according to a "picture" he had in mind. Several years ago, the Russian Ballet based his wonderful seventh symphony on a religious theme, and it still remained Beethoven. But in "Fantasia", Beethoven appears as someone quite different, and not to our liking. The unusual continuity of the whole piece, without the slightest break between movements, might have contributed to our irritation. But Beethoven was a musician; to disarm such criticism "Fantasia" can definitely claim to be an artistic appreciation and interpretation of music.

There was one exception—and this number was an exposition of the origin and evolution of life by a group of men of science, and accompanied by Stravinsky's music. At any rate, the item claimed to be the origin of life; actually it represented the origin of the earth and was followed up by the origin of life and its evolution up to the arrival, and comparatively sudden extinction, of the giant reptiles of the Mesozoic. It is obvious that Mr. Disney carefully consulted authoritative astronomers and biologists before embarking on this unique production. The film lost its cartoon qualities and became almost real—Amœba engulfing its prey, Hydra somersaulting, other aquatic life, Pterodactyls, the small-brained herbivorous Brontosaurus and the fierce, carnivorous Tyrannosaurus, all coming to life in their true perspective so far as science is able to visualize it. This number will probably appeal most of all to men of science; despite certain detailed faults, it hus much more than entertainment value, as indeed has the whole film.

The Profession of Chemistry

In his presidential address to the Society of Chemical Industry (*Chemistry and Industry*, July 12, 1941), Prof. J. C. Philip outlined the history of recent efforts made by chemists to bring order and co-operation into their ranks by the formation of some kind of federal union. These efforts began at the close of the War of 1914–18, at the instigation of the late Lord Moulton, and are still continuing. So far they have had little result, and their recapitulation would have little interest except to chemists and possibly to other professional men who desire to substitute co-operation for extreme individualism and *laisser-faire*. Sectionalism, as Prof. Philip says, has undoubtedly been a determining factor in the want of success, but another, not mentioned by him, has been inability to choose the right type of leader, a defect which seems to be common in many democratic organizations. A learned professor, however brilliant in his own special field, will fail unless he possesses the power of influencing other men's minds, and his failure may lead to the emergence of the self-appointed type of leader who has a gift for oratory, that harlot of the arts, *et prœterea nihil*.

At the present time, the movement towards union is in charge of a Chemical Council, which was set up in July 1935, under a deed of agreement between the Chemical Society, the Institute of Chemistry, and the Society of Chemical Industry. Each of these societies is represented by three delegates, and there are also three co-opted representatives of industry, nominated by the Association of British Chemical Manufacturers. The Council undertakes the general administration of the funds available for the educational and scientific publications of the constituent bodies. The library of the Chemical Society, which has long outgrown the narrow confines of its rooms in Burlington House, is to remain the property of that Society but to be administered by a joint committee of the various bodies contributing to its maintenance. The Council disposes of funds that for the present seem adequate, but these would have to be largely supplemented were the old idea of a Chemistry House to materialize. A year ago a supplementary agreement was signed

extending the validity of the original agreement until 1947. Progress in collaboration has recently been effected by instituting a scheme which facilitates joint membership of two or three of the societies under payment of a reduced total fee ; and by giving members a wide choice of publications up to a specified limiting value. The provisions of the deed aim primarily at 'roping in' as many as possible of the 14,000 (?) scientific chemists now practising their profession, with the view of promoting the progress and status of chemistry in its threefold aspect of science, profession and technical applications. Nothing appears to be said about the obligations of the profession to the community, but there is little doubt that these could be and would be far better met by a united profession than by what has been called "a disunited rabble".

Rockefeller Foundation's Gifts to the National Central Library

At a time when the Trustees of the National Central Library are faced with difficulties beyond the normal, as a result of the loss by enemy action of about half its books and the greater part of its London building, the emergency grant of £2,200 which has recently been made by the Rockefeller Foundation comes as a most welcome gift. Some of the books lost will be irreplaceable, but, fortunately, many of them can be bought as the demand for them arises. The timely aid of the Rockefeller Foundation will be appreciated by many thousands of persons who will benefit by the valuable additional service thus placed at their disposal. The grant is also another illustration of the practical sympathy of the United States with the difficulties which have to be dealt with by those responsible for the work of cultural institutions in the British Isles. By helping the National Central Library, the Rockefeller Foundation is indirectly helping all other libraries which make use of the national service. The Rockefeller Foundation is also continuing to provide money for the upkeep of the Bureau of American Bibliography at the National Central Library.

Physical Society: Annual General Meeting

The sixty-seventh annual general meeting of the Physical Society was held on July 25 in the lecture theatre of the Science Museum, with Prof. Allan Ferguson in the chair. The reports of the Council and of the treasurer were adopted and the following officers for 1941–42 elected. *President :* Dr. C. G. Darwin ; *Hon. Treasurer :* Dr. C. C. Paterson ; *Hon. Secretary (Business) :* Dr. W. Jevons *: Hon. Secretary (Papers) :* Mr. J. H. Awbery ; *Hon. Librarian :* Dr. L. C. Martin ; *New Members of Council :* Prof. E. N. da C. Andrade and Dr. H. Shaw. Prof. Ferguson will undertake the duty of acting-president until Dr. Darwin is able to take office. The Council has to record a very successful year's work in difficult circumstances. Despite exceptionally heavy losses by death, the membership of the Society is scarcely affected, standing at 1,070 members at the end of 1940, as compared with 1,084 members twelve months earlier.

For the science meetings of the Society, the Council has adopted a new policy which has been justified by its complete success, the majority of the meetings having been devoted to discussions and to lecture-surveys. Discussions have been held on colour, the liquid state, the electrical and general physical properties of plastics, and the teaching of the fundamentals of electric and magnetic theory. Lecture-surveys have been given on contact-angles (Prof. Allan Ferguson), anemometry (Prof. P. A. Sheppard), gravity meters (Dr. J. McG. Bruckshaw), the magnetic hysteresis cycle and its interpretation (Prof. L. F. Bates), and some mechanical properties of glass (Prof. W. E. S. Turner). An outstanding event was the formation, within the ambit of the Society, of a Group for the discussion of scientific and technical problems relating to colour. The Group has already held three very profitable meetings, and its success encourages the initiation of similarly constituted groups for the discussion of problems of special interest to experts on the subjects to which the groups are devoted.

A Clouded Yellow Butterfly Invasion

One of the most interesting entomological features of the summer of 1941 is the invasion of clouded yellow butterflies (*Colias croceus* or *Edusa*) from the Continent which, since the first week of July, have been seen in Lancashire and Cheshire and various other parts of the north of England. This immigration has nothing to do with the War ; it is one of the more spasmodic immigrations of insects which occur from time to time, the classic example being the 'great *Edusa* year' of 1877, when flights ranged from the Orkneys to Land's End and Ireland. Several were seen in 1933, 1926, 1913, 1872, 1864, 1862 and 1859 and odd specimens in the north in other years like 1930. The greenish-white variety *helice* Hubn. has also been seen, while the rarer pale clouded yellow (*C. Hyale*) was observed in 1860, 1872, 1891, 1900–1, and at least one specimen has been noted at Ness, west Cheshire, during the present immigration of clouded yellows. A few clouded yellows from south Europe reach the south of England almost every year, arriving during May or June ; third brood larvæ are sometimes found in autumn on trefoil, lucerne or clover, and attempts at hibernation have been noted, but there is no record of surviving the winter here. Excepting in 1892, the common and pale clouded yellows are seldom abundant immigrants together.

Mineral Composition of Crops

It is generally recognized that the mineral composition of crops has an important bearing on human and animal health, and increasing attention is being paid to the interrelationships between such fields of investigation as soils, fertilizers, plant composition and the nutritive value of food. Although it is true that several nutritional diseases can be directly traced to the deficiency or excess of particular minerals, as yet the data are usually quite insufficient for the laying down of direct recommendations for agricultural practice. A valuable review and com-

pilation of this subject has been made by K. C. Beeson entitled "The Mineral Composition of Crops with Particular Reference to the Soils in which they were grown" (U.S. Dept. Agric. Misc. Pub. No. 369). The question is approached from two main aspects, namely, the soil characteristics associated with nutritional diseases in man and animals, and the various factors which affect the mineral composition of plants. In the first case, bone diseases, anæmias, goitre and selenium poisoning are among the instances discussed, while as regards the crops, fertilizers, climate, irrigation, age and part of the plant are shown to have an important influence on its chemical composition. More than six hundred references are quoted, which cover work carried out in various parts of the world. The publication concludes with extremely useful tables giving the chemical composition of a large number of crops, figures for many of the minor elements being included.

Rediffusion of Broadcasting over Electric Mains

In the report of the council of the Incorporated Municipal Electrical Association presented at the annual general meeting at York on June 12, one of the topics raised was broadcasting over the electric mains. In the last annual report it was intimated that in the event of legislation being promoted in this matter, the Association would press for the inclusion of a clause which would authorize electricity undertakers themselves to operate the rediffusion of broadcast programmes over their distributing mains if they so desired. Before the War, the business of rediffusion of broadcast programmes was a growing one and was, for some reason or other, outside the field covered by the electrical industry; but the Post Office was taking a special interest in the various rediffusion companies. The *Electrician* of June 13 says that it is probable that the Post Office holds the right to take over such wireless relays if it wishes, and that the further development of broadcasting over the mains might, without adequate protection, become a Government monopoly, with the added privilege of using, without cost to the Post Office, the already existing supply mains, which were put into the roads, etc., after long research and considerable expense by the electrical industry.

Earthquake of April 15 in Mexico

Further details are now available concerning the great earthquake which took place on April 15, 1941, in Mexico (see Nature, April 26, 1941, 507). It is stated in the news-magazine *Time* that at the tropical city of Colima, with a population of 20,000, the first shock caused the dam guarding the water supply to collapse, that it disrupted power lines and caused half the buildings in the town to collapse. The cathedral, rebuilt after the earthquake of 1932, was again destroyed, and during the night forest fires blazed round the town due to the scattering of the charcoal burning dumps by the earthquake. At least 36 people in Colima lost their lives. The shock was felt from Jalisco in the north to Oaxaca in the south, while in Mexico City just as lunch time was beginning, towers and signs swayed, church bells tinkled gently, windows rattled and pavements cracked. Mexico's tallest skyscraper, a seventeen-story office building at the corner of the Paseo de la Reforma and the Avenida del Ejido, shook and cracked and a five-story section of glass and facing stone collapsed. Fires broke out, one destroying the El Monte lumberyard after firemen had fought the blaze for six hours. No one was killed in Mexico City though 800,000 dollars worth of damage was done to property. Altogether the earthquake caused near 2,000,000 dollars worth of damage to property and at least 84 people were killed, including 27 at Tuxpan in the State of Jalisco.

The U.S. Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the epicentre of this earthquake and its aftershocks from instrumental reports from twenty-one seismographic stations. The epicentre of the first earthquake at 19h. 9m. 53s. G.M.T. on April 15 was at lat. 18·8° N., long. 103·0° W., which is some 70 miles south-east of Colima, and the depth of focus normal. Strong aftershocks on April 15 at 23h. 42.6m. G.M.T. and on April 16 at 1h. 37·9m. G.M.T. had their epicentres slightly north of that of the main shock.

Beit Memorial Fellowships for Medical Research

At a meeting of the Trustees of the Beit Memorial Fellowships for Medical Research held on July 23 it was noted that out of the thirty present fellows thirteen have already been seconded at their own request for more direct service during the War, and that six others have undertaken research work for Government departments on problems arising out of the War.

The following elections of new fellows were made, all with permission for each fellow to be seconded at any time for war duties: *Senior Fellowship* (£700 a year) to Dr. T. R. R. Mann, to continue his work on intracellular metallo-protein compounds, expecially of red blood cells, at the Molteno Institute of Biology, University of Cambridge. *Fourth Year Fellowships* (£500 a year) to Dr. J. F. Danielli, to continue his work on the permeability of muscle fibres and of capillaries, at the Biochemical Laboratory, University of Cambridge; Dr. C. O. Hebb, to continue her studies of physiological problems in relation to high altitudes, at the Department of Physiology, University of Edinburgh; Dr. H. Lehmann, to continue his work on the influence of shock and of the suprarenal glands on glycogen synthesis, at the Biochemical Laboratory, University of Cambridge. *Junior Fellowships* (normal value £400 a year) to Dr. E. F. Gale, to study bacterial amine production as a cause of non-specific infantile diarrhœa, at the Biochemical Laboratory, University of Cambridge; Mr. W. Holmes, to study the regeneration of nerve fibres after injury, at the Department of Zoology, University of Oxford; Dr. M. F. Lockett, to identify renal pressor substances responsible for experimental high blood pressure, at the Pharmacological Laboratory, University of Cambridge.

Public Health in Venezuela

THE outstanding developments in Venezuelan public health since the establishment of the autonomous Ministry of Public Health and Social Welfare in February 1936 include the building up of a well-trained full-time staff, a tuberculosis control division with child and adult dispensaries in the capital and seventeen other cities, a school hygiene X-ray division, a national institute of puericulture, a malaria control division, a yellow fever preventive service, division of sanitary engineering and ankylostomiasis, and cancer and leprosy institutes. Among the more recent developments have been the creation of a Social Service Division in 1938, the opening of its school in 1940 and the increase in the number of beds in hospitals.

Institute of Fuel

MR. W. M. SELVEY has been elected president of the Institute of Fuel in succession to Sir John Greenly, as from October next. Mr. Selvey has been very closely identified for many years with the development of fuel economy in all forms, but more particularly in connexion with the electric power stations in Great Britain and abroad.

The Melchett Medal for 1941 has been awarded to Dr. Clarence A. Seyler, of Swansea, as some recognition of his work on coal and its constitution.

Sir David Milne-Watson, Bart., has been nominated president of the Fuel Luncheon Club for the coming session in succession to Lieut.-Colonel W. A. Bristow, who has occupied the chair for the past two years.

College of the Pharmaceutical Society

IT is good news that although the College of the Pharmaceutical Society has obtained temporary accommodation in Cardiff and the Departments of Nutrition and Pharmacology have been housed at the National Institute for Research in Dairying, Reading, research work is still going on. This is evidenced by the annual report for 1940 of the research departments of the College of the Pharmaceutical Society (pp. 30, Heffer and Sons). Items of interest are: the influence of cooking on the vitamin content of foods; the components of acriflavine; the structure of γ-sugars; the quantitative determination of cinnamon and cassia and methods of assay of prolactin, heparin and suprarenal cortical hormone.

The Marine Biological Laboratory, Plymouth

WE learn from the Secretary of the Marine Biological Association that the Plymouth Laboratory, which a few months ago sustained heavy damage through enemy action (NATURE, **147**, 411; 1941), has now been restored to working order. Extensive emergency repairs have been carried out, accommodation for research workers is once more available and there are limited opportunities for work at sea in the Association's motor boat. It has, however, been necessary to transfer the greater part of the library to other quarters, and only the recent volumes of current periodicals can now be consulted.

Comet van Gent (1941d)

A CABLEGRAM has been transmitted from Dr. W. H. van den Bos, Union Observatory, South Africa, announcing the discovery of a comet by Dr. H. van Gent, Bosscha Observatory, Lembang, on May 27.96965 U.T. At the time of discovery its position was, R.A. 18h. 01·9m., Dec. $-40°$ 07′, and its daily motion was 5m. 15s. west, 41′ north. It was diffuse, with central condensation or nucleus, and the tail was less than 1° in length. The magnitude was 11. An orbit has been computed by Dr. F. J. Bobone, the elements of which, and also an ephemeris, are given below.

T	1941 September 3·362 U.T.		
ω	84° 13′		
Ω	256 42		1941·0

Prof. Strömgren suggests that Comet Bernasconi-Zagar, discovered at Bologna on June 17, is probably Comet van Gent.

Announcements

THE Annual Congress of the Royal Sanitary Association of Scotland will be held in Glasgow on September 16–17.

A PAN-AMERICAN League against Cancer has been founded in New York under the presidency of Prof. Angelo H. Roffo, director of the Institute for Experimental Medicine at Buenos Aires.

THE subsidization of private growers of cinchona in India is being urged by the India Chemical Manufacturing Association, which points out that, if anti-malarial treatment is to be provided in India, at least 6 lakh lb. of quinine will be required annually. The present consumption is about 2 lakh lb., of which India produces about 70,000 lb., the remainder being imported from abroad.

A new national natural history society chiefly for scouts, guides and schoolboys under eighteen years of age, to be known as the Grey Owl Society, was recently formed at Haslemere, Surrey, by D. P. Faux, who is honorary secretary, the other officials being: *President*, Eric Hardy; *Editor*, P. Shaw Baker; *Hon. Treasurer*, Miss Watson. The society is to have a half-yearly journal called *Wild Life*, to publish instructive pamphlets, organize lectures, outdoor meetings, correspondence, an identification service and possibly nature study examinations. An explanatory booklet is now in the press. The secretary's address is 5 Lion Lane, Haslemere, and membership is also open to people over eighteen.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

"The Philosophy of Physical Science"

I HAVE been re-reading Sir Arthur Eddington's recent book with great admiration, but also with grave doubts as to whether his philosophical position is not wholly unsound. I think he employs the word 'epistemological' in at least two different senses ('epistemological-in-form' and 'epistemological-in-substance'), and the resulting confusion of thought is disastrous to his proposed new philosophy of science.

His main contention (pp. 57, 58) is that all those laws of Nature that are usually classed as fundamental, as well as the values of the constants of Nature, can be foreseen "from epistemological considerations, so that we can have *a priori* knowledge of them". As examples of such laws he mentions (p. 39) special relativity, the uncertainty principle of Heisenberg and the modified mechanics of indistinguishable particles.

The relativity principle was not in the first instance founded on, or even suspected from, epistemological considerations: it was founded on the Michelson-Morley and other experiments. After these had resulted in a sufficient number of failures to detect absolute velocity, Einstein proposed a hypothesis which can be expressed in a great variety of ways, as for example:

(*a*) The laws of Nature involve only relative velocities.

(*b*) It is impossible to determine an absolute velocity in space.

(*c*) It is meaningless to talk of simultaneity at distant points.

While the mathematical contents of these three statements are practically identical, their forms are very different. There is nothing epistemological in (*a*) and not much in (*b*), but (*c*) is distinctly epistemological-in-form. Eddington considers that (*c*) could have been foreseen epistemologically even "if the result of the Michelson-Morley experiment had not instigated a scrutiny" (p. 39). If he is right, then (*c*) is not only epistemological-in-form, but also epistemological-in-substance. But surely he is wrong. The Michelson-Morley experiment did more than instigate a scrutiny; it disclosed one of the 'brute facts' of Nature, and it is on this fact that proposition (*c*) depends for its very existence; if the experiment had not turned out as it did, there would have been no proposition (*c*). Thus (*c*) is not *a priori* knowledge in the sense of the rationalist philosophers, or even in the sense of Eddington, who defines *a priori* knowledge as "knowledge which we have of the physical universe prior to actual observation of it" (p. 24). In its substance (*c*) is just as empirical as (*a*) and (*b*); indeed all three statements comprise virtually the same substance—an interpretation of the Michelson-Morley etc. experiments.

There is a shorter cut to the same conclusion. If light travelled with infinite velocity, it would clearly not be meaningless to speak of simultaneity at distant points. Hence (*c*) includes, as the greater includes the less, the proposition that light travels with finite velocity. Can Eddington seriously claim that this is "knowledge which we have of the physical universe prior to actual observation of it"?

It is the same with Eddington's other instances, which are taken from the quantum theory. They can all be enunciated so as to be epistemological-in-form, but no matter in what form they are enunciated, their substance is empirical; their content is knowledge extracted from observation—in this case from studies of the spectra of black bodies and of atoms.

Eddington seems to me not to trouble about the substance of laws, but to tie the label "epistemological" on to every law which can be so enunciated as to be epistemological-in-form (as so many empirical laws can be). He then claims for his labelled laws an "altogether different status from physical hypotheses" (p. 39), as well as certain special properties peculiar to epistemological laws. He tells us, for example, that such laws "have a security that is denied to those that can only be reached empirically" (p. 19), and that "whatever is accounted for epistemologically is *ipso facto* subjective; it is demolished as part of the objective world" (p. 59).

These properties, it seems to me, can only be claimed for laws which are wholly epistemological-in-substance; that is, which are entirely free from any empirical ties with the outer world, and so are *a priori* in the sense defined above. Not a single one of the laws which Eddington labels as epistemological seems to me to qualify for this category.

After Eddington's last step quoted above, there is a clear road open to his conclusion that "the purely objective sources of the objective element in our observational knowledge are *life, consciousness, spirit*. . . . The purely objective world is the spiritual world; and the material world is subjective in the sense of selective subjectivism" (p. 69). But is it not obvious that we cannot attain such far-reaching results merely by stating the results of experiment in such a way that they are epistemological-in-form?

J. H. JEANS.

Park House,
Wanstrow,
Somerset.
June 20.

IT is difficult to answer Sir James Jeans within the space of a letter; but I will begin with his statement (*c*). This is simply a statement of fact. Except in cosmological investigations, quantitative statements depending on distant simultaneity are meaningless because the reckoning has been left undefined. In the last thirty years distant simultaneity has been *by-passed*; and there is now no inducement to find a meaning for it even if we could. Among other consequences 'intrinsic similarity' of two systems necessarily means that they are related by a Lorentz transformation, that being the only criterion of similarity which does not presuppose a definition of distant simultaneity. The definition of similarity provides the norm from which are reckoned the strains which describe various kinds of dissimilarity.

In this way the Lorentz transformation has become an ingredient in the comprehensive scheme of formulation of knowledge, covering molar and microscopic physics, which comprises the equations and constants commonly classed as 'fundamental'.

Thus far I have been considering method, not observational facts. I agree with Sir James Jeans that the Michelson-Morley experiment discloses "one of the 'brute facts' of Nature". Let us try to express this 'brute fact' not in the terminology of 1887, or even of 1905, but as it appears in 1941. To say that the experiment will give a null result if strains are properly eliminated has become a tautology. The new fact is that, with the experimental precautions adopted, strains *are* eliminated.

Facts of this kind are of immense importance for progress; but they occur in other parts of physics, and we do not make a song about them. The pessimist may say: How can I keep an eye on all possible sources of disturbance, near and distant, visible and invisible? The optimist attends to a few major sources and trusts that the rest will balance out. Sometimes the optimist is right, sometimes the pessimist. In astronomy the optimist has assumed that the stars really are in the direction in which we see them—that their light rays take a straight course to the earth. The pessimist might reflect that, unless the light rays go a great deal straighter than they do in the gravitational field on the earth, they will tie themselves in knots in interstellar space. His fears are groundless, and it is of immense importance to discover that they are: but I do not know of any astronomical text-book which mentions this. The laying of bogies is an important side of progress; but it is not the practice to associate with the fundamental laws of physics an obituary of bogies.

If, following Jeans, we are to distinguish between the form and substance of a law, the substance is, I suppose, concerned with what obeys the law. In elementary cases we can indicate the substance by pointing—we point to certain objects in the sky and say that those are what Kepler's laws apply to. But as physics has grown more complex a change of method has occurred, which I think Jeans does not take into account. Description has been substituted for pointing. The change was scarcely avoidable, since we have to indicate not only an object but also the conditions in which the effects predicted by the law would occur undisturbed. The elements in the description can only be defined by their properties, that is, by the laws they obey; so that we find ourselves chasing our own tails in a purely formal system. Jeans's objection is that we know a great deal about the universe which is not mere tail-chasing. I answer: Yes; but that is not the knowledge epitomized in the existing scheme of fundamental laws and constants. Their function is to supply a system of formulating it.

I have been considering what the Michelson-Morley experiment discloses, not what it might have disclosed. Perhaps I should also consider the situation which would arise if the experimenters have let us down badly and the true result is that which Michelson originally expected. In the present terminology we should say that there is a strain depending systematically on the velocity. I think that (after gathering up the wreckage of present-day theory) we should find ourselves faced with a universe far more complicated than we have lately imagined: so that relatively we should be thrown back many centuries, and much further investigation would be necessary before we could see how the scheme of epistemological law applied. Another possibility is that it might be sufficient to introduce an extra law governing the strains and whatever was the cause of them. Presumably this would be a truly objective law—the first to be discovered. Whilst my scientific epistemology would be unaffected, the conclusions referred to in the last paragraph of Jeans's letter would be upset, since they are a commentary on the fact that no truly objective law has been found. However, so long as the effect is only imagined and not discovered, I need feel no apprehension.

Reactivity of the Sulphur Linkage in Animal Fibres

MAKING use of a reaction discovered in this laboratory[1], Elöd, Nowotny and Zahn[2] claim to have shown that disulphide bond breakdown is neither an essential preliminary to the setting of strained animal fibres, nor a necessary cause of supercontraction. Wool fibres were heated with water in presence of mercury at 80° C., hydrogen sulphide being liberated and mercuric sulphide formed as a result of disulphide bond breakdown:

$$R.CH_2.S.S.CH_2.R + H_2O = R.CH_2SH + R.CHO + H_2S.$$

Although 45 per cent of the total sulphur was removed in 19 days, suggesting that 90 per cent of the disulphide bonds were hydrolysed, the fibres showed no tendency to contract in either boiling water or boiling hydrochloric acid at *p*H 2, and their setting power (in an unspecified medium) was unimpaired.

The failure of the mercury-treated fibres to show supercontraction might be due to the occurrence of setting reactions in the unstretched fibres during the prolonged heating in water at 80° C., especially as mercury compounds have been shown to be specially effective in promoting cross-linkage formation[4]. Elöd himself refers to the tanning action of the mercuric sulphide[2], but if cross-linkage formation is invoked to explain the absence of supercontraction, the difficulty of accounting for unimpaired setting properties becomes more acute. There can be no doubt, therefore, that if Elöd's observations are correct, the present theory of the chemical mechanism of permanent set[3] is invalidated. In consequence, it seemed justifiable to re-examine the properties of mercury-treated fibres.

Because of its higher sulphur content, human hair was used in preference to wool, in order to prolong the reaction with water and allow the course of disulphide bond attack to be followed more readily. After purification with alcohol, ether and distilled water, the fibres were heated for several days at 80° C. with distilled water and purified mercury in a quartz tube. Fibres were removed at intervals and their setting power determined in the usual way, each fibre being stretched 40 per cent in cold water and then set by immersion in boiling 2 per cent borax solution for 30 minutes. The set retained by the fibre after various times of release in boiling water was determined by measuring its air-dry length at intervals, drying being allowed to proceed in absence of tension. Typical data are given in the accompanying table, from which it is clear that the ability of

animal fibres to acquire a permanent set decreases with increasing time of heating with water and mercury at 80° C.

Time of treatment with water and mercury at 80° C.	Percentage set after release in boiling water for: 0 min.	2 min.	15 min.	30 min.	60 min.
Untreated	40·2	24·0	22·3	22·5	22·2
6 d. 2 hr. 15 min.	40·4	19·0	17·6	17·4	17·1
8 ,, 23 .. 6 ,,	40·2	15·9	15·2	14·9	14·4
13 ,, 3 .. 50 ,,	40·3	12·9	12·2	12·0	11·5
22 ,, 2 .. 30 ,,	40·3	2·9	1·6	1·1	0·5

In accordance with setting theory, too, the treated fibres showed an increased power of supercontraction in boiling 2 per cent borax solution. For example, fibres which had been treated for 22 days contracted 42 per cent after 40 minutes boiling, whereas the length of untreated fibres remains unaltered under similar conditions. Contrary to Elöd's observations, therefore, supercontraction is promoted and set prevented when sulphur is removed from animal fibres by the combined action of water and mercury at 80° C. The present conception of the chemical mechanism of permanent set[3] remains valid, and the theoretical superstructure which Elöd has erected need not be discussed.

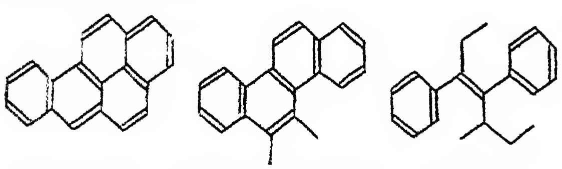
Carcinogenic Agent without the Condensed Carbon Ring Structure

IN an earlier publication[1] the formula of the highly active synthetic œstrogenic analogue, stilbœstrol, was contrasted with those of œstrone and chrysene. The figures in this earlier letter in NATURE indicated that by ring closure in the case of stilbœstrol a condensed carbon ring compound similar to œstrone on one hand and to chrysene on the other could be obtained. Since all the known carcinogenic hydrocarbons possess the condensed carbon ring structure, it was decided, by analogy with œstrone, to see if it were possible to break down the condensed ring structure of the carcinogenic hydrocarbons without losing all carcinogenic activity.

Two groups of twenty-five adult stock male mice, one group of coloured, the other of albino mice, have been painted twice weekly with a 0·3 per cent solution of α-ethyl-β-*sec*-butylstilbene in benzene. Fig. 1 indicates how this substance can be derived from either benzpyrene or dimethylchrysene by fissure of the rings.

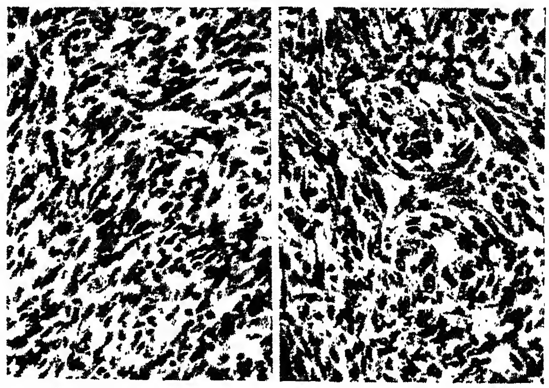


BENZPYRENE DIMETHYLCHRYSENE α-ETHYL-β-*sec*-BUTYLSTILBENE

Fig. 1.

Two tumours have developed in these groups. One of the seven coloured mice (*CM* 160/40) surviving after 12 months painting, had a tumour on the edge of the painted region at the back of the neck. It grew more rapidly than was expected, reaching a size of 2 cm. × 2 cm., and became necrotic. A second tumour was found in one of the thirteen albino mice (*CM* 44/40) surviving after 15 months painting. This was a slow-growing tumour situated subcutaneously on the rump 2 cm. distant from the painted area. At autopsy it was hard and 1·5 cm. × 0·5 cm. in size. In neither case were any metastases found.

Histologically, the two tumours were very similar (see Fig. 2), being spindle-celled and malignant. The first one was a spindle-celled carcinoma, the second a sarcoma. Attempts to transplant the first were unsuccessful, but fragments of the sarcoma were implanted in ten stock albino mice and, at the time of writing, two months after implantation, tumours have developed in five of the ten. The largest tumour (2 cm. × 1 cm.) has been sectioned and proved to be similar to the parent sarcoma.



CM 160/40 (×200) *CM* 44/40 (×250)

Fig. 2.

A further group of fifty mice is now being painted with the same compound in an attempt to confirm the results, and other chemically related compounds are being investigated. If the results are confirmed, we believe that this is the first instance of carcinogenesis associated with painting a hydrocarbon without a condensed ring structure.

No positive results have been obtained by painting mice with diphenylhexane, diphenylhexadiene or diethylstilbene for shorter periods (6–9 months) in the same way; and no tumours were found on painting groups of twenty-five coloured mice twice weekly with 0·3 per cent acetone solution of 4 : 4′-dihydroxy-αβ-diethylstilbene (stilbœstrol), 4 : 4′-dihydroxydiphenylhexane (hexœstrol) or 4 : 4′-dihydroxystilbene for similar short periods. Stilbœstrol when given by this method was unexpectedly toxic, and none of the mice survived for more than three months.

Stimulation of Neuron Proliferation by Means of Growth Hormone

IN further investigation of the theory I have already outlined[1,2] that by means of the growth hormone preparation it may be possible to stimulate artificially the proliferation of prospective cerebral neurons in mammals, I have used 385 albino rats in an attempt to improve the level of the psychical functions of the animal.

The rats were subjected in pregnancy to subcutaneous injections of growth hormone preparation 'Antuitrin G' and 'Phyone'. The offspring investigated at birth showed an increase of 18·7 per cent in body weight, 36 per cent in cerebral hemispheres weight, 21 per cent in thickness of the cerebral cortex, 70·4 per cent in volume of the cortex, 9·27 per cent in density of cells, and 86·5 per cent in number of cells per volume of cortex, as compared with the controls. All these increases are statistically significant.

A certain number of animals reached maturity, and proved to show an increase of 14·8–27·6 per cent in cell density, and 38–40·6 per cent in total number of cortical neurons, as compared with the controls. These increases are statistically significant.

It is concluded that in mammals the growth hormone preparation administrated in pregnancy does increase the number of cortical neurons in the offspring.

A full report on this work will be published elsewhere.

The Hamburgh Parsley

THE Hamburgh parsley, known also as the large-rooted parsley, turnip-rooted parsley or parsnip-rooted parsley, has been developed on the Continent for its root instead of the usual leaves. It is a vegetable which deserves much wider use in Great Britain both for its pleasant flavour, which most nearly resembles celeriac, and as a particularly rich source of vitamin C during the winter months.

There are two varieties, the late, with long thin roots, and the early, which forms a compact root like a short thick parsnip. The latter is the more useful type and is the form on which these notes are based. At Cambridge stocks have been grown from Danish, French and German seed, the Danish producing the best-shaped roots. The roots are a very pale yellow colour, almost white, and they form an excellent vegetable either boiled, used in vegetable stew or soup, or grated and eaten raw.

Cultivation is the same as for parsnips, but the roots are easier to dig and remain free from canker. From a sowing made on April 18, usable roots were obtained in October and remained in good condition when stored until the end of the following April. The roots appear to be unaffected by frost and can be left in the ground and dug as required for use, or can be stored in a clamp. No figures for the rate of cropping have been obtained, but it should be reasonably high judging by the appearance of roots lifted from observation rows. The Hamburgh parsley will grow on poor soil, having thrived on the hot dry gravel at Cambridge.

The greatest merit of this vegetable as a war-time crop is its rich content of vitamin C which is available during the winter months. It has been found by a nutritional laboratory that roots which had been stored for 5 months still contained about 21 mgm. of vitamin C per 100 gm., a much higher value than is known in any root vegetable except swedes.

Plankton as a Source of Food

MANY will have read with interest the recent proposals[1] concerning the possible use of plankton for human or livestock food. There is, however, an entirely different aspect of the subject which ought to be considered and would at least in one connexion be of far easier application. I refer to the possible use of plankton—especially freshwater phytoplankton—for *plant* nutrition, and the 'connexion' is the small vegetable gardener who has to water his plants. If he does this repeatedly or at least frequently in what is often the easiest way, namely, from open tanks or pans or from the A.R.P. buckets we are supposed to have outside our doors, he may be adding a very useful amount of nutrient matter to the soil, at least during periods of plankton 'maximum'. In hot sunny weather, just when watering is most necessary, great algal activity (which may turn water green in a day) may be maintained week after week and used almost nightly by merely leaving the green or brownish investment on the inside of the vessel intact when fresh water is added.

It seems probable that in these present times when farmyard manure is often impossible to obtain, such frequent planktonic additions, the component individuals of which often go on growing and dividing on or below the surface of the soil but ultimately will be washed down and decomposed, would go at least some way towards remedying the deficiency—without extra trouble or expense to the gardener. Only a sunny situation and wide open vessels are necessary, and sometimes the addition of a nitrogenous and phosphatogenous solution (for example, a very few drops of liquid manure).

It has been my intention for some months past to experiment along these lines and find out if the suggested benefit is really considerable, especially under other than optimal conditions; but as I have as yet had no opportunity to do this with proper controls, and am unlikely this year to have the time even to read all the pertinent literature[2], I record these ideas and intentions in the hope that they may be taken up and made use of by someone else. Other, connected possibilities which have come to mind, but about which I can find no published *ad hoc* research, I would gladly impart to or discuss with any responsible person who may be interested.

SURFACE SOIL THICKNESS AND COTTON DEVELOPMENT

By Dr. A. Sreenivasan,

Institute of Plant Industry, Indore

In profile studies with the black cotton soil in Malwa, it has been observed that the thickness of the productive surface layer differed appreciably even between adjoining rich and poor fields. Often, the nature of the surface soil also varied, particularly in regard to openness, permeability and crumb structure. It therefore appeared probable that the friable loose surface soil in a field was closely associated with its fertility.

The normal drainage water from fields during rains removes with it a certain amount of the finer fractions of the upper soil layers, but beyond this, it is essential to conserve the surface soil from erosion losses. A knowledge of the depth of the surface soil which it is necessary to conserve will be of value in determining the efficiency of erosion control.

During the 1939 kharif season, a small plot (8 ft. × 8 ft.) experiment was carried out to ascertain what depth of the surface soil is optimum for cotton development, and whether it is enough to conserve the existing soil of a field or whether importation of surface soil from a rich field will be of any benefit to a poor field.

The test was carried out on the Institute fields, 12*D* and 27*S.E.* The former is a field of medium fertility and is well drained, while the latter is a badly drained field with very poor crop growth. The rich surface soil required for the experiment was taken from field 42*N*. Addition of average, loose, hand-gathered surface soil from the same field was made in thicknesses of 1, 2, 3, 4 and 5 in. respectively. Addition of surface soil from the rich field was made in thicknesses of 2 and 5 in. only.

There were five randomized blocks in each of the two fields with eight plots per block. Experimental plot size was 6 ft. × 6 ft. containing six rows of plants one foot apart, thus leaving a non-experimental margin of one row on each side and one foot at each end of the plot. There were 3-ft. paths between and all round the plots which were edged with bricks. The seeds (variety *Malvi* 9-20) were sown by dibbling.

Table I.

	Control-untreated	Thickness in inches of surface soil added from: Same field					Rich field	
	(1)	One (2)	Two (3)	Three (4)	Four (5)	Five (6)	Two (7)	Five (8)
Well-drained field (12*D*)								
Yield of seed cotton (in ounces)	34·8	55·3	63·3	58·0	57·0	58·0	44·3	77·8
		Critical difference ($P = 0{\cdot}01$) = 4·6. Order of merit: (8) (3) (2) (4) (5) (6) (7) (1)						
Poorly drained field (27 *S.E.*)								
Yield of seed cotton (in ounces)	9·5	16·8	16·0	17·0	24·5	28·3	15·0	24·0
		Critical difference ($P = 0{\cdot}01$) = 2·5 Order of merit: (6) (5) (8) (2) (3) (4) (7) (1)						

Table II.

Loose surface soil from:	Carbon per cent	Nitrogen per cent	Available K_2O per cent	Available P_2O_5 per cent	Exchange capacity m.e. per cent	Pore space c.c. per cent	Structural coefficient	pH
Poorly drained field (27 *S.E.*)	0·407	0·064	0·0037	0·014	38·0	51·6	0·44	8·6
Well-drained field (12*D*)	0·436	0·076	0·0039	0·013	38·8	53·9	0·52	8·4
Rich field (42*N*)	0·604	0·077	0·0044	0·013	40·1	55·8	0·58	8·7

The yields of seed cotton for the different treatments are given in Table I.

Addition of loose surface soil from the same field increased the yield of cotton in both the fields, but while in the well-drained field the best result is obtained with the addition of a 2-in. layer of surface soil, the poorly drained field shows in general increasing differences in yield with increased additions of surface soil, a 5-in. layer giving the maximum yield. Lack of proper drainage naturally results in surface wash during periods of heavy rainfall and consequent loss in the fertility of the field (*cf.* the yield figures for the control plots of the two fields). Besides, the difference between the two fields in their response to treatments also shows the relative richness of their surface soils. This fact is further borne out by the results of laboratory examination of these surface soils (Table II).

Addition of surface soil from the rich field also increased the yield significantly in both the fields, the response being better with the greater thickness. But, considering the cost of importation, this is not likely to be more profitable compared to addition of soil from the same field.

These results bear out the value of the conservation of surface soil that may be achieved by erosion control.

FORESTRY IN NYASALAND

FROM the annual report of the Forestry Department of the Nyasaland Protectorate for the year ending December 31, 1940 (Govt. Printer, Zomba, Nyasaland, 1941), it appears that a happy relationship has been established between that Department and the Agricultural Department. The Forestry Department has to some extent undertaken duties which bring it into direct relationship with the agricultural habits and practices of the local population. The Conservator reports that during the year the Provincial Agricultural Officer visited the southern course for special discussions, and the Director of Agriculture addressed the Foresters at the close of the course. These courses are annual ones given to the subordinate forest staff by divisional forest officers and lasting 10–14 days. The aims of the forestry policy in Nyasaland have been already discussed in NATURE.

The formation of village forests has proved a most important departure in the Protectorate, for they have caught the imagination. It is stated that the number of registered village forest areas has now reached 4,677 and that the majority are well cared for by the headman and villagers. In some of the earliest formed, systematic thinnings are now being undertaken with assistance from the district forestry staffs. It will be noted that this management is on the same lines as practised in the management of the communal forests in France. But a still closer connexion between the forest staff and the agricultural community exists through the participation of the former in land use problems and in activities to introduce simple reforms in the agricultural methods of the people. It is said that results have been excellent in parts of the Southern Province and that whole communities have changed over from mound planting (on hill-sides, productive of serious erosion) to ridge planting on the contour. Hill slope closure and stream bank protection are serious questions in parts of the Protectorate, and a plea for increased agricultural production has emphasized the need for much better control by native authorities over the opening up of new land for cultivation. For example, one of the commonest phases of these unchecked, ignorant cultivation practices it is stated is that "in some regions very steep hill slopes, of only ephemeral utility for agriculture, are still being cleared for planting maize".

It appears only fair to a forest staff to point out that, so long as dangerous activities of this kind are allowed by the administration to be practised unchecked, the danger to the Colony concerned as a whole may be so great as to render nugatory the efforts of a Department in obtaining sanction to the formation of forest reserves with a view to their professional management ; or even to the future success of the village forests, to the inauguration of which the Conservator of Forests in Nyasaland has devoted so much energy with such refreshing and creditable results.

OXFORD MEETING OF THE WORLD CONGRESS OF FAITHS

BY SIR FRANCIS YOUNGHUSBAND, K.C.S.I., K.C.I.E.

RECONSTRUCTION is in the air : the need for building a New World Order ; and the need for a sound spiritual basis on which to build it. This was the subject discussed at the meeting held at Oxford during June 27–July 2 of the World Congress of Faiths. The main idea of the Congress is to promote the spirit of fellowship and to promote it through religion ; not through one religion only, but through all religions working in collaboration and in concert, each retaining its own individuality, its own special forms and beliefs, but all willing to work with others in the great world-reconstruction now before us.

With this as its general aim, the World Congress of Faiths had for its special subject for discussion at this sixth annual meeting the interdependence of religion and the political, economic, social and educational aspects of the New World Order.

The Congress was officially welcomed to Oxford by the University. The inaugural meeting was addressed by the chairman of the Congress, Sir Francis Younghusband, by Señor Madariaga, Sir Hassen Suhrawardy (Muslim adviser to the Secretary of State for India) and the Rev. Canon Grensted. Others who spoke at the sessions of the Congress included Lord Samuel, Dr. Gilbert Murray, Mr. Yussuf Ali (translator of the Koran into English), Lord Davies, Diwan Runganadhan (another Indian adviser to the Secretary of State for India), Baron Palmstierna (formerly Swedish Minister to the Court of St. James's), the Warden of All Souls, Prof. W. Adams, and Miss Maude Petre, a well-known Roman Catholic writer.

Both the addresses and the discussion on them were on a high level. As a result of the meeting it was decided to invite the principal leaders in the Hindu, Buddhist, Jewish, Confucian and Muslim worlds to make pronouncements so far as possible on similar lines to that issued by the Pope and acceded to by the leaders of the Roman Catholic, Anglican and Free Churches in Britain. But the Congress also passed a resolution advocating the addition of a

clause favouring freedom of religious worship and expression.

It was evident to those who had attended previous Congresses, as well as the present, that distinct progress had been made. The Congress is now well established and able to draw support from the most influential persons in the country. Moreover, a growing cohesion among its members was noted, and it is safe to predict that some years hence a meeting of the Congress on a far greater scale might be held. There would necessarily be a meeting of the present belligerents to settle the terms of peace between them. After this limited conference, a more general conference would probably follow at which representatives from most of the peoples of the world would assemble to decide upon the future political structure of the New World Order, whether a reformed League of Nations or some type of federation. This would be an opportunity which should be seized. The World Congress of Faiths should organize a meeting of the most prominent representatives of all the great world religions to devise means by which the political New World Order may be given that spiritual drive and that steady and sustained spiritual support without which it can never endure. Annual meetings of the Congress will be held as heretofore; but the greater meeting some years hence will be the goal towards which they will deliberately be made to tend.

MATHEMATICAL PROBLEMS IN SEISMOLOGY

A. BLAKE has recently directed attention to many outstanding problems in mathematical seismology (*Trans. Amer. Geophys. Union*, 1940). The following problems are, more particularly, mentioned: (1) Problems in the theory of seismic waves due to inhomogeneities in the media and other causes, and to new methods available for the study of the interior of the earth. (2) Problems of instrumental seismology including the new strain meter and rotation seismograph. (3) Problems relating to the complexities encountered in determining the response of engineering structures to the motion of a strong near earthquake. (4) Problems of statistical seismology, especially the periodicity problem. In many cases Blake states that seismological calculations may be performed by machines such as the differential analyser and punched card machines.

Concerning strong-motion problems, Blake says that the analysis of the response of a structure into characteristic or normal components satisfying linear equations depends on the treatment of the strain-energy function as quadratic. But the purpose of investigating the response to destructive earthquake motions requires consideration of strains much exceeding the limits within which Hooke's Law remains valid. According to the author the linear theory can then only be used as a first approximation and the effects of the various components of ground motion cannot be treated separately. The Rayleigh dissipation function may be important, but the case of small damping including the existence of normal modes of oscillation has been encountered in the case of buildings, bridges and tank towers. The paper will act as a signpost towards further progress in mathematical seismology.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TEACHER OF GENERAL SCIENCE SUBJECTS (PHYSICS AND CHEMISTRY), AND A TEACHER OF MATHEMATICS—The Principal, Luton Technical College, Park Square, Luton (August 9).

DIETITIAN—The Secretary-Superintendent, Middlesex Hospital, London, W.1 (August 9).

ASSISTANT INSPECTOR OF SCHOOLS—The Education Officer, Education Office, Katharine Street, Croydon (endorsed "Assistant Inspector of Schools") (August 11).

ASSISTANT SECRETARY FOR EDUCATION—The Secretary for Education, Education Offices, 6 Lampton Road, Hounslow, Middlesex (August 23).

COLLEGE LIBRARIAN—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (September 13).

PROFESSOR OF MATHEMATICS—The Registrar, University College of Swansea, Singleton Park, Swansea (September 13).

PART-TIME LECTURERS AND INSTRUCTORS IN ALL SUBJECTS OF MECHANICAL, ELECTRICAL AND PRODUCTION ENGINEERING—The Principal, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17.

NATURE

SATURDAY
AUG. 9, 1941

REORGANIZATION OF THE NATION'S WAR EFFORT

THE concern with the organization of production and the strategy of the War, both diplomatic and military, which found expression in the debates on the campaign in Crete and more recently on war production arises entirely from the desire to strengthen the hands of the Prime Minister, from the general belief that insufficient use is still being made of our resources of materials and men, and that, great war premier as he is, he cannot win the war without long-term strategic plans or unsupported by the application of the keenest critical minds the Empire can supply. The Government showed a lamentable lack of appreciation of this position in a recent debate on production when the Minister of one Department and the Parliamentary Secretary of another were left to meet criticisms which came from all parts of the House of Commons and raised questions far wider than any departmental issues. The insistent call for a better distribution of effort, more effective planning and a more scientific method of organization was deliberately ignored, nor can it be said that this call was fairly met by the Prime Minister in his statement opening the subsequent debate on July 29.

Such neglect is disservice to the Prime Minister himself. Appreciation of the magnificent service he has rendered and continues to render to the cause of freedom throughout the world is in no way diminished by a growing conviction that his service would become even more invaluable if he could be relieved of some of the heavy burdens the present system and organization place upon his shoulders. Moreover, the changes recently announced—the appointment of an advisory committee to the Production Executive and the attachment of the regional boards to the Production Executive—like the appointment of Lord Beaverbrook as Minister of Supply and Mr. Morrison's arguments against a Ministry of Civil Defence are suggestive more of shreds and patches than of a concerted policy and the formulation of a grand strategy. Taken with the rather petulant reply of the Prime Minister himself to questions regarding the recent appointment of Mr. Oliver Lyttelton as Minister of State resident in the Middle East, they are calculated to arouse, rather than to dispel, public misgivings.

That the time has come for recasting strategy and replanning the War is widely believed. Parliament clearly means to see that the Prime Minister is provided with the best political, diplomatic, administrative, industrial and military machine the Empire can create. It is determined that the burden is no longer to be on one man alone, and the demand for a small War Cabinet of men of highly developed critical faculties, moral courage, clear and imaginative minds and a good working knowledge of strategy and industrial planning grows stronger every day. Only from such a Cabinet can we look for what is the more imperative as help from the United States increases—a

definite decision as to the kind of war we mean to fight, how and where we mean to fight it, and the forces required for success.

Such decisions are essential to the devising of an adequate and flexible plan and to the organization of the home front whether for civil defence or production. They cannot be expected of the bureaucratic mind and there must be utter ruthlessness in sweeping away the type of official who regards the State or some department of it as his own affair, in which no one outside has any right to interfere except under his orders. That this is the temper of the nation was shown clearly in the recent debates on production with their demand for leadership. Examples could be multiplied over almost the whole field of national endeavour to show how for lack of imaginative and constructive leadership opportunities are being missed, enthusiasm damped, and the national effort checked of its full power.

In these circumstances, Lieut.-Colonel Clive Garsia's "Planning the War", just published as a "Penguin Special", is of particular interest, and may well serve to focus constructive thought upon the aims of Allied strategy, the means by which they are to be achieved and the organization of all our resources to that end. Obviously, there is much that the Government cannot disclose of both planning and strategy, but there are too many signs of the absence of planning where it should be evident for uneasiness in this respect to be lightly dismissed. A trenchant article by Sir William Beveridge, for example, in *The Times*, pointed out that the formation of a national fire-fighting service was at least six months overdue when it was initiated, and disposed convincingly of Mr. Morrison's arguments against a Ministry of Civil Defence.

That co-operation between existing Ministries and local authorities is still imperfect, that the degree of readiness in different areas does not correspond to the degree of danger, and that the Fourth Arm of our defences needs a single head as much as the other three arms is scarcely questioned by those who have experience of severe air attack. A similar impression prevails in the field of production through failure of the Government to use its compulsory powers and give positive direction and not merely advice, for example, in the numerous problems which arise in the concentration of industry and the direction of labour and enterprise from distribution or non-essential work to the war production industries. Indeed, the omission to take the nation into its confidence, to explain exactly why certain changes in occupation, in habit, or diet are required and then firmly and impartially enforce them, whether the use of brown bread in place of white, the discouragement of inefficient forms of food production or conversion, such as pig-keeping, poultry and eggs, the allotment of shipping space to non-essentials, or the elimination of retailers whose trade is too small for economic distribution, is doing more harm to the national morale than the Government realizes or admits.

Consciousness of this danger is the true source of some of the concern regarding the Ministry of Information itself, but uneasiness at the co-ordination of our war effort is widespread. Too many problems of civil defence, priorities, fuel, agriculture, and so on, appear to be handled on departmental lines with little indication of relation to an overruling plan and strategy. Evidence of waste of man-power and materials is widespread, and there is growing impatience at excessive leniency towards offenders in such matters as absenteeism, mismanagement and offences against rationing. Too often the people hunger for leadership and are not fed.

It is not to be expected that the incomparable leadership of the Prime Minister should be all that is provided. Something of that quality must reach down from him through all ranks and to all sections of society. Nor is the long-range planning or even the medium-range planning essentially the task of a War Cabinet. That should rightly be delegated to professional subordinates whose special and sole business it is, whether industrial, naval, military, scientific or political. This is the first characteristic of the system of planning outlined by Lieut-Colonel Garsia. It starts from the bottom and works upwards, not from the top downwards as in the present system which the Prime Minister defended in his statement on January 22. Free from both planning and executive functions, except in so far as its members participate individually as chairmen of co-ordinating planning committees, the vital responsibility of the War Cabinet he suggests is to give decisions on matters of major importance.

The second essential feature of Colonel Garsia's system is that instead of being based on past experience—what he calls the static method—it takes account of the potentialities of the situation ; not merely the resources available at the moment, but those which might be made available to implement a strategic concept which when the problem is first approached appears to be quite unattainable. This is what he terms dynamic planning, and he quotes a passage from Mr. Churchill's "World Crisis" which illustrates how this concept was present in the Prime Minister's mind more than twenty-five years ago.

This system of what Colonel Garsia terms automatic planning thus originates at the perimeter and not at the head of the organization. Stimulating and utilizing creative thought at all levels, it also

facilitates rapid and decisive elimination of the less promising alternatives as well as the integration of activities while the plan is still nebulous. Responsibility for medium- and long-range planning and the essential staff work involved are delegated to a series of planning committees each of which covers one of the specific fields into which the whole is necessarily subdivided. Use of the proper technique and submission of a reasoned appreciation and plan covering the field for which each committee is responsible enables the co-ordinating Control Planning Committee, the chairman of which would be the secretary of the Committee of Imperial Defence, readily to synthesize a comprehensive plan for the consideration of a War Cabinet relieved of the detailed work and executive duties which might prevent proper attention to major strategy in every field of operation.

This War Cabinet represents the apex of the system. Small and selected for acute analytical minds rather than representing special interests or political parties, and limited to at most three or four in addition to the Prime Minister and the Minister of Defence, under the Prime Minister's leadership, untrammelled by military or other duties, unburdened by quasi-departmental responsibilities, it would supervise and direct all these activities, intervening with decisive authority wherever required. It would, in fact, be in keeping with the Cabinet visualized in the Haldane Committee's report and with the proposals advanced in 1938 by Brigadier Sir Edward Tandy in his lecture before the Royal Society of Arts on "The British Cabinet and its Increasing Burden".

"Planning the War" is a timely and significant contribution to the theory of planning and organization which cannot but make a special appeal to the scientific worker. Moreover, apart from the range and complexity of our existing war effort, our growing relations with the United States impose fresh problems and burdens on our war organization. We cannot expect that partnership to yield its fullest results unless co-operation is effectively organized and planned, and Anglo-French experience prior to 1914 as well as in the opening of the present war well attests the truth of Colonel Garsia's emphasis on the importance of planning in Anglo-American co-operation. Indeed he goes so far as to assert that Anglo-American planning has not yet come into existence.

It is possible to criticize Colonel Garsia's proposals as somewhat too theoretical. They appear, however, in the main to be in harmony with established principles of scientific management, and his emphasis on the importance of sound organization and efficient technique is most timely. There is real danger that the conduct of the war may be endangered and victory delayed by imperfect or inferior staff work in these fields. If we are to make the most effective use of our resources and advantages, our staff work and organization must be equal if not superior to that of our enemy, and there will be widespread agreement with Colonel Garsia's view that our primary requirement to-day is not tanks and guns, but a central organization and technique competent to plan the combined war effort of the British Empire and of the United States.

The main objectives of any reorganization are not in dispute. It should secure the clearest possible definition of strategic purpose in the broadest sense. Planning machinery staffed by specialists must be devised to secure the swift and orderly fulfilment of that purpose, measuring its requirements and marshalling in its service in turn all the resources of man-power and materials available in Great Britain, its allies or partners. Such proposals as those of Colonel Garsia are designed to strengthen, not to weaken, the Government; to avert dangers which a continuance of the present system is likely to precipitate; and to place the Government in a better position to investigate rapidly and constructively the whole conduct of the war and of the allocation of the war output with the one object of organizing that total effort for speedy victory. Above all it is intended to lift from the Prime Minister's shoulders something of the great burden resting upon them and to enable him to assert even more decisively and inspiringly the full vigour of his matchless leadership. That is the real purpose behind the criticism voiced in Colonel Garsia's book, in the debates in the House of Commons, and in many quarters outside, on civil defence, on man-power and on production. The warmth with which Mr. Churchill's subsequent promise of a full and comprehensive statement in a third day's debate on production in public session was welcomed is an eloquent testimony both to the universal regard for his own magnificent leadership, and to the determination that any shortcomings in the organization and management of our war production must be rectified with the utmost dispatch and without regard of persons.

The statement so eagerly awaited was made in the House of Commons on July 29. Mr. Churchill outlined the steps which were taken to prepare a general programme of munitions production at home and in relation to imports, which was approved by the War Cabinet in March last. He then dealt, one by one, with the more specific criticisms which were made in the earlier debate.

It was not to be expected that Mr. Churchill would give facts and figures of production, which would obviously be of the greatest value to the enemy, but he was nevertheless able to dispose of

some misunderstandings. Further, he expressed himself as satisfied with present arrangements—or at least, he declared he was unable to accept the suggestion for a Ministry of Production as likely in present circumstances to give better results. The delays and difficulties which had occurred are now, he said, largely matters of the past, and were due to such factors as the dispersion of factories, the dislocation caused by air raids, enforced changes of diet, and the dilution of skilled industry, and he remarked, "The House must, therefore, be content with my assurance that progress and expansion on a great scale are continuous and remorselessly spurred on".

The debate which followed was wound up by the Minister of Labour, Mr. Bevin. In reply to the criticism that so many skilled workers have been drafted into the Services, he reminded the House that the need for tradesmen in the Services is ten times as great as in any previous war. The Royal Air Force and the Navy have been able to train the great proportion of skilled workers they require, and he expressed the belief that the Army will do the same as its mechanical expansion proceeds. Dealing with industry, however, he agreed that there has been difficulty in building up supervision and management to cope with the sudden development of Governmental activity, and stated that he would like to see management "become a profession".

Looking back now on that debate and its predecessor, on matters of policy of vital import in the conduct of the war—debates which could not take place under a totalitarian regime—surely we can regard them as symbols of the vitality of democracy, and a guarantee that it is capable, when the time comes, of leading the nations to peace and prosperity.

NATURALISM AND SUPERNATURALISM

An Essay on Nature
By Frederick J. E. Woodbridge. Pp. xi+351. (New York: Columbia University Press; London: Oxford University Press, 1940.) 20*s*. net.

THIS is an unusual book, attractively written and well worth reading. It is a direct and general statement of belief such as one seldom gets from a modern philosopher. At this late day a new faith is necessarily suspect. Prof. Woodbridge would probably not claim that his was new, but he could well claim a sane and judicious outlook and a freshness of expression which throws new light on old truths.

Prof. Woodbridge's starting-point is that of naturalism, a candid and, so far as possible, a complete acceptance of the world of fact. This means that Nature is all that can be discovered by the help of experience. Nature "is the field of knowledge and as that field she is pre-eminently the familiar visible world. The problems of knowledge are all problems of formulating her coherences" (p. 331). On this view it is a profound mistake to divide the natural world into two parts, one that is seen but not understood, another that is understood by means of scientific theory but not visible. A consequence of the stress laid on the unity of Nature is the conclusion that the relations of the sciences have been generally misconceived. "Nature, not the wit of man, gives to knowledge its integral character. This suggests a science of nature which is neither physics nor chemistry and the like nor the social sciences and their like and which is, in a somewhat Hegelian way, a special science because restricted to what is not specific, but general. Had the history of the sciences been kind in its preference for Greek words this special science might well have been called 'physics' and all others summed up under 'metaphysics', subdivided in terms of specific subject matter" (pp. 58–59). If Prof. Woodbridge is right, this general science scarcely exists as yet.

Granted a candid recognition of facts, Prof. Woodbridge argues that one among those to be recognized is the fact that men pursue other ends besides knowledge, ends that may be summed up as 'happiness'. For knowledge Nature is primary, but for happiness, secondary. "The important fact is that the pursuit of happiness leads to the question whether that pursuit is worth while. That is the great question that has haunted mankind for ages. In a way it is an odd question. Nobody ever seems wholly content to take the positive fact that happiness is pursued as an answer" (p. 334). If the pursuit is to be justified, it is justified by faith in (not knowledge of) the 'supernatural'. Prof. Woodbridge prefers the term 'supernatural' to the more popular term 'ideal', although, as he says, it is commonly disliked and supposed to imply superstition. But superstition is not faith; it is the attempt to deal with the supernatural by blackmail or bribery. The distinction is that between Job, who kept faith though he were to be slain, and Saul, who consulted the witch of Endor. This is perhaps the main conclusion of the book, that supernaturalism is not the antithesis of naturalism but its necessary complement. On one hand, claims to knowledge

are invalid unless they follow from an acceptance of the realm of facts; on the other, human interests are unsatisfied, even the interest in knowledge, without the realization that the realm of facts is in itself incomplete. In other words, without faith in something else, for which Nature is secondary, there is no motive for trying to understand Nature.

There is one criticism to be made, concerned rather with the method of statement than with any substantial point. The author speaks of Nature as being pre-eminently the visible world and this is to a large extent true. Such a statement, however, obscures the fact that the physical sciences could be studied by blind men possessing the other senses, but not by beings possessing sight only. Measurement, as Berkeley pointed out long ago, is of tangible objects even though referred to visible objects and expressed in visual terms. Newton's laws of motion describe the operation of tangible things. If they are applied to the stars, it is because these visible objects are treated as though they were tangible. A. D. Ritchie.

PHYSICS OF OIL PROSPECTING

Geophysical Prospecting for Oil
By L. L. Nettleton. Pp. xi+444. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 35*s*.

In the last few months a number of very welcome books have been published in the United States on the subject of geophysical prospecting. Of these, the present work fulfils a very useful purpose, as it is written mainly for the layman, that is the petroleum geologist and the petroleum engineer. These, as a rule, do not participate actively in this branch of oil prospecting; nevertheless they should be in a position to appreciate the possibilities and limitations of the various methods which can be employed for this purpose, and also they should be able to understand the implications of any geophysical survey. In such a subject as geophysical prospecting, in which the technique is advancing rapidly, there are obvious difficulties in the way of the layman who wishes to keep in touch with the latest developments. Nettleton's book, giving a reliable and co-ordinated picture of the present state of geophysical prospecting in relation to oil, should do much to remove these difficulties and to form a background against which future developments can be assessed.

In common with most books on the subject, it is divided into four sections, three of these being devoted to the most important methods of oil prospecting, namely the gravitational, the magnetic and the seismic methods respectively, and these occupy nearly 90 per cent of the whole. The remaining section, devoted to the electrical applications (including electrical coring) and to miscellaneous methods, is contained in less than fifty pages and is by far the weakest part of the work. The book is generously illustrated, and for those who wish for further detail on the main points, each section is furnished with a brief bibliography of the more important papers on the subject.

From the author's preface, it appears that the book had three objects. The first, and most important, is to present a reliable picture of the principles and practice of geophysical prospecting for oil, primarily for the layman. At the same time, as a second object it is tentatively suggested that much of the material will serve as a useful reference for the specialist. Finally, and really part of the first aim, the writer hopes to give the student an appreciation of geophysical maps, the immediate product of any survey.

On the whole, the first of these objects has been attained reasonably well, and in certain chapters extremely well. Thus, the section dealing with direct gravity-measuring instruments is an excellent example of the standard suitable for the beginner, particularly the geologist. It is profusely illustrated with twenty figures in less than thirty pages, the diagrams themselves being, in many cases, almost self-explanatory. These, supplemented by short paragraphs in the text, give a clear, if somewhat simplified, picture of the modern instrument. On the other hand, certain parts are treated in a more mathematical manner, for example, the theory of the torsion balance, the vertical force variometer and many of the factors involved in interpretation. Although the treatment is elementary, it is likely to prove heavy for the non-mathematically trained geologist, and is more suitable for the physicist. The second object is obviously incompatible with the first, for those aspects which are likely to appeal to the beginner cannot contain the detail to which the specialist will have occasion to refer. Certain features of use to the professional are certainly included, such as the average physical properties of rocks, gravity tables, charts and tables for terrain corrections, etc., but the list is far from being comprehensive. Formulæ for the computation of effects are very sparse, referring only to the simplest shapes, and these are used mainly to illustrate certain factors involved in the interpretation of results. The most serious criticism which can be made is the lack of examples of actual geophysical surveys. In the gravitational and magnetic sections, not a single

geophysical map is given, while in the seismic section only two or three examples appear.

Nevertheless, the petroleum technologist who is interested should derive much benefit from the book, for the mathematical treatments are usually preceded by a section devoted on the physical principles involved, and the physicist should find it an easy introduction to the subject. Both, however, would find it necessary to supplement the volume with practical examples before the true purpose of the book was achieved.

J. McG. Bruckshaw.

MODERN SURVEYING

(1) Plane and Geodetic Surveying for Engineers
By the late Prof. David Clark. (Text Books of Civil Engineering.) Vol. 1: Plane Surveying. Third Edition, revised and enlarged by James Clendinning. Pp. xvi+620. (London: Constable & Co., Ltd., 1940.) 27*s*. 6*d*. net.

(2) Engineering Surveys
By Harry Rubey, Prof. George Edward Lommel, and Prof. Marion Wesley Todd. (Engineering Science Series.) Revised edition. Pp. xv+322+142. (New York: The Macmillan Company, 1940.) 15*s*. net.

(3) Route Surveying
By Prof. George Wellington Pickels and Prof. Carroll Carson Wiley. Second edition. Pp. xv+427. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 21*s*. net.

(4) Introduction to Mine Surveying
By W. W. Staley. Pp. vii+276. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1940.) 21*s*. 6*d*. net.

IN a general text on surveying, as is pointed out by the author of one of these books, there is little room for originality except in treatment. Regarded as a branch of mathematics or as a conventional system of making, recording and plotting earth measurements, the subject is one which demands strict adherence to well-established rules. The improvements in instruments made possible by better designs and by increasing precision of manufacture whereby the degree of accuracy has risen from 1 in 5,000 to 1 in 30,000, cause changes to take place such as the substitution, in certain cases, of traversing for the more laborious method of triangulation.

(1) As an example of a text-book which has been maintained in close relation to modern tendencies, Clark's "Plane and Geodetic Surveying" may be cited. The third edition of vol. 1 deals with practically all the knowledge required of the average civil engineer and is distinguished by the clear terms in which instruments and methods have been described and explained. To bring it into line with recent developments the editor has added a chapter on linear measurements and has extended the original section on traversing so that it is now represented by one dealing with field work and another with office computations. Other important additions include instruction on the theory of errors, on road transition curves and on the important aid to hydrographic surveying provided by the echo-sounding apparatus.

(2) "Engineering Surveys" deals in a more concise but equally clear way with the same general subject from the point of view of the present-day engineer. In the revised edition, the excellent Macmillan Mathematical Tables have been retained and one giving the average air correction for barometric levelling temperature has been added. Otherwise, changes made in the text are matters of detail introduced to ensure a practical up-to-date presentation of the subject eminently suitable either for instruction or for casual reference.

(3) "Route Surveying" is more limited in scope and deals with the essentials of railroad, highway and other route surveys as required for transmission lines, pipe lines, canals, drainage, etc. The major changes introduced include extensive new matter on circular curves and spirals and on the string-lining method as applied to the re-alignment of existing railroad curves. Although the spiral is usually regarded as complex and difficult, the presentation of it here from the point of view of change of curvature makes it appear but slightly more difficult than a simple curve, and the treatment is probably as complete as any so far available.

(4) In "Mine Surveying", another branch of the subject is presented. It is a new book devised to make good the deficiency of works on the subject and is largely based on a questionnaire sent to prominent companies in North America engaged in gold, silver, copper, lead and zinc mining. The author, from his own experience, has supplemented and organized the important information thus obtained as to present-day practice. As the reader is assumed to have a basic knowledge of plane surveying, the text is wholly devoted to the specialized methods and instruments devised for use in mines, and represents well-authenticated practice of the present day.

CHARLES CHREE AND HIS WORK ON GEOMAGNETISM*

By Prof. S. Chapman, F.R.S.

CHARLES CHREE, a son of the manse, an Aberdonian scholar brilliant in classics as well as in science, distinguished later at Cambridge as a mathematical expert on the theory of elasticity, in 1893 took up new and very different labours as superintendent of the magnetic and meteorological observatory at Kew. When he retired in 1925 he was president of both the international organizations concerned with geomagnetism.

British Contributions to Geomagnetism

In the earth sciences, most of all, international co-operation is a necessity for progress; yet each nation may feel pride in its own contributions to the common stock. In geomagnetism Britain has a long and distinguished record. Queen Elizabeth's hydrographer Robert Norman was the first to measure the magnetic dip (1576); her physician William Gilbert wrote "de Magnete" (1600), the first modern scientific treatise. Gellibrand, Gresham professor, discovered the secular magnetic variation (1634); Halley made the first scientific voyages (1698–1700) to measure the magnetic declination, and also constructed the first magnetic chart (1701). Graham, the London instrument maker, discovered the transient magnetic variations (1724).

In the nineteenth century Sabine fostered the British Colonial magnetic observatories, discovered the 11-year cycle in geomagnetism, and like Broun of Trevandrum, made notable studies of the lunar geomagnetic tide. Balfour Stewart was the first to realize the existence of the ionosphere as the primary source, through dynamo action, of the daily magnetic variations (1882). Schuster applied Gauss's method of spherical harmonic analysis to these variations (1889), and developed Stewart's dynamo theory (1908). Maunder made brilliant studies on the connexions between the sun and magnetic storms (1904–16).

Chree and his Contemporaries

Chree, contemporary with Schuster and Maunder, was in this distinguished succession, and his name will endure in the history of geomagnetism. Other notable contemporaries were Bauer, the initiator and first director of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, and Schmidt, van Bemmelen and Moos, the directors of the magnetic observatories at Potsdam, Batavia and Bombay; like Chree, they were not content with maintaining a high standard of accuracy in the magnetic measurements under their charge; they had also the energy, ability and inward impulse to undertake the scientific discussion of their records.

Chree maintained the reputation of Kew as a magnetic centre of the first rank; he standardized magnetic instruments, trained many young men to use them, notably on polar and other magnetic expeditions, and gave immense time and effort to the discussion not only of the Kew data, but also of records obtained by four Antarctic expeditions. He brought to his work, besides untiring industry and devotion, a meticulous attention to detail, and a clear, critical and scrupulously exact mind.

Geomagnetism has need of men of widely different gifts: of the organizer and administrator; of the man of affairs, who can influence Governments or private benefactors to provide resources for the science; of the navigator and explorer; of the instrument designer and maker; of the patient, skilled and resourceful observer, often far from social and technical centres; of the faithful computer, zealous for detailed accuracy; of the investigator, theorist and writer.

Bauer was a man of enthusiasm and energy, who took wide views and realized great projects; but his eagerness to reach conclusions, where sometimes judgment was better deferred, met a useful corrective in Chree's critical detachment, which later administered some cooling draughts to my own youthful optimism. Schuster, though perhaps not Chree's equal as a mathematician, nor with a tithe of his detailed knowledge of geomagnetism, could make brilliant sorties into the subject, leading to striking theoretical conclusions; by labours trifling compared with Chree's, he lifted some parts of the subject to a new level. Maunder had a daily familiarity with the sun's aspect, as well as with the Greenwich magnetic records; this enabled him to perceive certain remarkable associations between the sun and magnetic storms; his work stimulated Chree to some of his finest achievements.

Whereas Schuster, Maunder and Bauer were ready to make hypotheses, Chree held that a theory was not necessary as a guide to research, and he refrained from speculation; nevertheless his work was greatly influenced by the speculations of Maunder and Arrhenius on the magnetic effects of streams of particles emitted from the sun.

* From the first Charles Chree Address to the Physical Society, delivered on July 25. The latter part of the address, referring to the future of world magnetic surveying, is not included in this summary.

DOES GEOMAGNETIC DISTURBANCE LAG BEHIND SOLAR ACTIVITY?

Chree showed that when there were many or large spots on the sun, days of geomagnetic calm were rarer than on days of no or few spots; but the difference was very slight. He concluded that geomagnetic disturbance could not depend directly in any large degree on the simultaneous area of spots on the sun, but that his results might easily be reconciled with Arrhenius's view that geomagnetic disturbance lagged two or three days after the solar cause, because of the time taken by the solar particles to travel from the sun to the earth.

To study this possibility, Chree in 1908 devised a new method of great value and power, which I have called the *method of superposed epochs*. He examined how, on the average, the sunspot area varied during a number of intervals, each of 4 days, and each ending with a day of selected geomagnetic character (either calm or disturbed): thus in the averaging, the epochs of these selected days were superposed. Later he and his followers considered intervals of greater length, extending after as well as before the selected superposed days; he

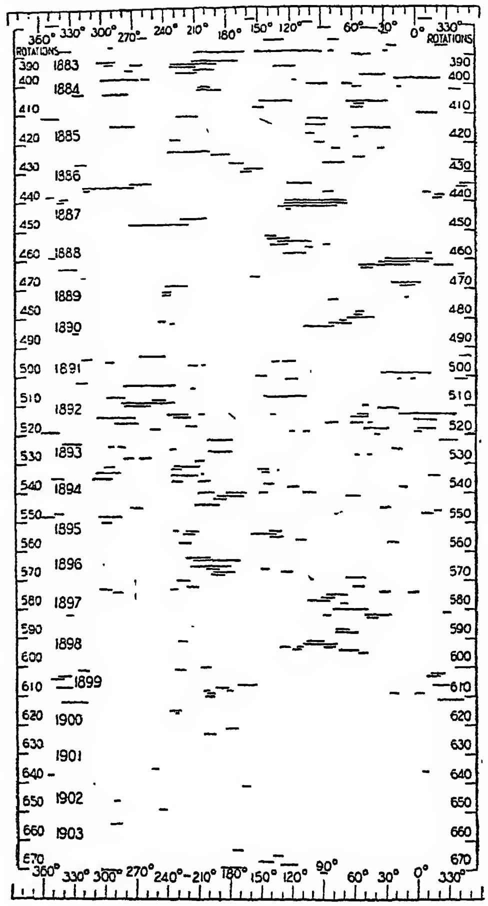

Fig. 2.

DISTRIBUTION OF MAGNETIC DISTURBANCES, 1882–1903, ACCORDING TO THE HELIOGRAPHIC LONGITUDE OF THE CENTRE OF THE SUN'S DISK AT THE TIME OF THEIR COMMENCEMENT. After E. W. Maunder.

also considered in the same way the average variation of the geomagnetic activity before and after days of selected sunspot character.

In the hands of Maurain, and later of Stagg, using much more material than Chree, results were thus obtained which leave little room for doubt that on the average, on days of notable geomagnetic disturbance, the sunspottedness is declining from a maximum value attained two or three days earlier (Fig. 1); but the sunspot peak is shallow, and may be obscured by accidental circumstances if the material is too scanty to average these out. This is the less surprising because sunspots are at least not the sole cause of magnetic disturbance, which sometimes occurs during intervals of many days free from sunspots.

THE 27-DAY RECURRENCE TENDENCY

Chree's method was thus successful in elucidating an important interrelationship between solar and geomagnetic data. Chree also made a still more

beautiful and successful application of his method, to test a time relationship appearing in the geomagnetic data by themselves. This is a tendency for geomagnetic conditions of exceptional calm or exceptional disturbance to recur, generally with diminished intensity, after about 27 days; it is therefore called the 27-day recurrence tendency.

This had been recognized by Broun (1858) and by many others after him, who had directed attention to a 'period' of 27 or 28 days in magnetic and auroral phenomena. But its nature was not understood, and even its existence was often doubted or overlooked, until Maunder rediscovered it and demonstrated its real character in 1904. Some of his predecessors had thought it might be connected with the lunar month; but Maunder, deeply imbued with a knowledge of the succession of both solar and magnetic phenomena, was quite clear as to its solar origin. He regarded the sun as intermittently ejecting limited streams of corpuscles which, like water from a fire-hose, may sweep the earth at successive rotations of the sun, if the emission is sufficiently prolonged. His presentation of his discovery was made with this idea in view, and from the point of view of the solar physicist.

His demonstration was graphical, by means of a diagram (Fig. 2) in which the solar longitude of the centre of the sun's disk (as viewed from the earth) is measured along a succession of horizontal lines drawn at equal vertical intervals; each line represents one rotation, occupying 27·3 days, of a certain standard meridian on the sun. If during any such rotation one or more geomagnetic storms occurred, Maunder marked the part or parts of the horizontal line for that rotation, between the solar longitudes corresponding to the beginning and end of the storm; the remaining part of this and other lines, not corresponding to the occurrence of a storm, was obliterated (or rather not drawn). The diagram shows that many of these storm lines fall nearly on the same vertical, corresponding to nearly the same solar longitude, and indicating a recurrence after an interval of one or more solar rotation periods of 27·3 days.

Maunder's diagram, however, has no necessary connexion with the sun; it forms what I have called a *time-pattern*, in which successive horizontal lines represent merely successive intervals of 27·3 days. Maunder adopted the 27·3 day interval because it is the mean rotation period of sunspots; but he recognized that if a sequence of storms occurred at a slightly different interval, this would be clearly shown by a slight displacement of their successive 'lines' to the right or to the left. In his diagram the sequences of storm lines are rarely so clear cut as to show whether the usual interval is 27·3 days, or half a day more or less than this. The identification of the mean recurrence interval with the solar rotation period is an independent step which, though highly probable, is a speculation rather than, like the recurrence interval itself, an established fact.

CHREE'S 27-DAY PULSE DIAGRAM

Chree applied his superposed epoch method to this question, using as the selected epochs days of

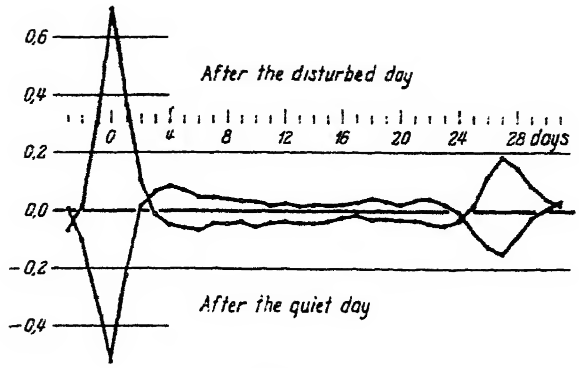

Fig. 3*a*.

AVERAGE CHANGE IN THE DAILY MAGNETIC CHARACTER-FIGURES, INDICATED BY THE DEVIATIONS FROM THE MEAN, FROM FOUR DAYS BEFORE UNTIL 31 DAYS AFTER A SET OF DISTURBED OR A SET OF QUIET DAYS, 1906–24. After Chree and Stagg.

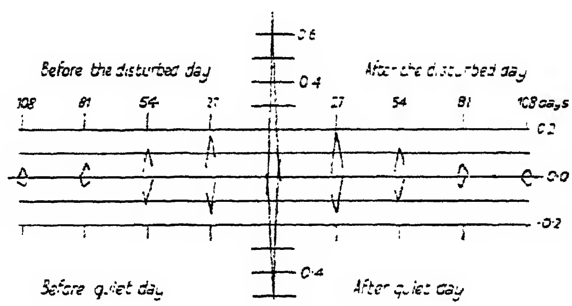

Fig. 3*b*.

AVERAGE CHANGE IN THE DAILY MAGNETIC CHARACTER-FIGURES, INDICATED BY THE DEVIATIONS FROM THE MEAN, FOR GROUPS OF DAYS AROUND A SET OF DISTURBED OR A SET OF QUIET DAYS (CENTRE), AND AROUND EPOCHS 1, 2, 3, 4 SOLAR ROTATIONS (OF 27 DAYS EACH) BEFORE AND AFTER. After Chree and Stagg.

either disturbed or quiet geomagnetic conditions. The daily data averaged for these days, and for the preceding and following days, were purely magnetic, namely the character figures internationally assigned as an index of each Greenwich day's geomagnetic activity. Some of his results are illustrated in Fig. 3 (*a*, *b*); the upper and lower parts of Fig. 3*a* refer respectively to the averages when the selected epochs are disturbed or calm. There are naturally peaks (positive or negative) for the selected days; there are also peaks 27 days

afterwards. This demonstrates the recurrence tendency and gives an indication of the recurrence interval, while involving absolutely no preconceived notion as to its length or significance.

Later Chree showed that there are corresponding peaks, of diminishing height (or depth) at about 54 and 81 days after the selected disturbed (or quiet) days, and also at similar intervals before them (Fig. 3*b*, where the averages for the days not near the peaks are not shown).

In my opinion this beautiful and brilliant application of his method is Chree's highest achievement and best gift to geomagnetic science ; his fame will always be linked with his pulse diagrams. This graphic product of his genius fitly finds a place on the Chree Medal.

Within the last two years Chree's method of superposed epochs has found useful applications to the time relationships of cosmic ray data, both as regards interrelationships with geomagnetic activity, and as regards the 27-day recurrence tendency in cosmic ray measures alone.

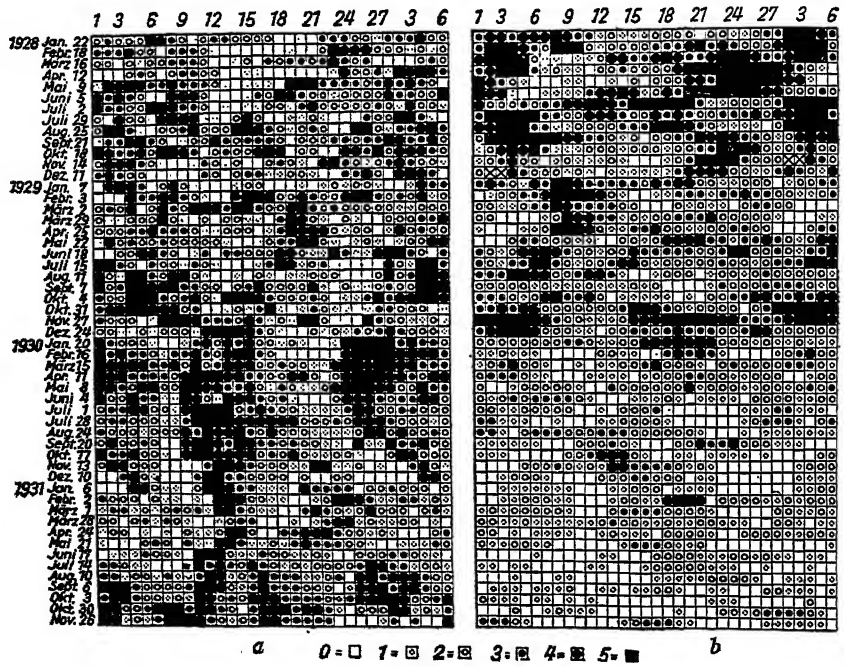

Fig. 4.

TIME-PATTERNS, FOR SUCCESSIVE ROWS OF 27 DAYS, ILLUSTRATING THE 27-DAY RECURRENCE TENDENCY FOR THE DAILY MAGNETIC ACTIVITY (LEFT, *a*) AND THE DAILY SUNSPOTTEDNESS (RIGHT, *b*). THE DATE FOR THE FIRST DAY IN EACH ROW IS INDICATED AT THE LEFT. After J. Bartels.

TIME-PATTERNS

Chree examined in great detail the significance of the recurrence pulses in his diagrams, to see, for example, whether they were due to the recurrence of a few notable days of the selected character, or merely to the occurrence of that character to a more moderate degree in a large proportion of days around the recurrence epoch.

In the course of such detailed investigation undertaken by Chree later, in conjunction with Stagg, differences were found between the pulse recurrences in 1920–21 and 1922–23. To examine these in more detail, they constructed two 27-day time-patterns, on which the international daily magnetic character figures were arranged in successive 27-day rows ; these figures were entered only for specially quiet or specially disturbed days, so that most of the 'pattern' was blank (as in Fig. 2); it showed the recurrence tendency in the same manner as in Fig. 2, by the grouping of disturbed or quiet days along the same verticals.

This diagram by Chree and Stagg forms a transitional stage between Maunder's diagram and later time-patterns constructed by Bartels. Maunder's diagram, despite its solar 'dress', was a true time-pattern, each row representing 27·3 days ; it showed the occurrence of outstanding magnetic disturbance, beginning and ending at different Greenwich times, and of varying duration ; the greater portion of the diagram was empty. The Chree–Stagg time-pattern was also mainly empty ; it showed specially quiet as well as specially disturbed periods ; but these were taken in units of the Greenwich day, and the horizontal range of

the diagram is 27 days (this does not prevent the diagram from showing a recurrence interval differing from 27 days; recurrences with a different interval would be shown by a slope of the sequences in successive rows).

Bartels by successive stages brought the 27-day time-pattern to perfection (1) by including all days, and (2) by indicating their magnetic character by a greater or less proportion of black (representing magnetic activity) in the square corresponding to each day. The result is shown in Fig. 4 (left); such a diagram represents an extraordinary concentration of knowledge, derived from magnetic observatories all over the world, over a period of nearly four years. The recurrence tendency is clearly shown by the 'columnar' distribution of the blackest and lightest parts of the diagram, though at least one recurrence sequence (near the end of 1930) is notably sloping, implying a recurrence interval of more than 28 days.

Bartels also applied his method to construct a time-pattern of solar activity, based on the daily *sunspot* number, as shown in Fig. 4 (right). The comparative study of the two diagrams for the same period is of great interest. The decline from the maximum (1928) of the sunspot cycle is much more strongly manifested by sunspots than by magnetic disturbance, and even in periods when both the sun and magnetic disturbance were active, their time-patterns are often very different. This shows that sunspots are often not a good index of the agencies on the sun that cause geomagnetic disturbance.

I feel confident that not only the method of superposed epochs, but also the study of time-patterns, has much still to contribute to geophysics and cosmical physics.

THE STUDY OF ENERGY-LEVELS IN BIOCHEMISTRY*

By Prof. A. Szent-Györgyi,
University of Szeged, Hungary

THE atom consists of a nucleus surrounded by a system of electrons. By sharing one or more electrons, atoms can join to form molecules. In such a molecule, as a rule, every electron belongs to one or two atoms. This is our idea of a single small molecule, and this picture has hitherto unconsciously governed our thinking in biochemistry.

The study of crystals and metals, however, has revealed the existence of a different state of matter. If a great number of atoms be arranged with regularity in close proximity, as for example, in a crystal lattice, the terms of the single valency electrons may fuse into common bands. The electrons in this band cease to belong to one or two atoms only, and belong to the whole system.

These bands or energy-levels are separated from possibly higher levels by forbidden zones. Under ordinary conditions all electrons are within the lowest band. If this lowest band contains the maximum number of electrons ($2n$, if the number of atoms is n), as is the case with insulators, the electrons will be unable to transport energy. If, however, one of these electrons is raised by the absorption of energy to a higher level, and comes to be in what we call an excited state, where it will move and transport its energy freely, it will be impossible to say which is the atom to which the excited electron belongs, and the whole system can be looked upon as activated. By falling back to the lower level the electron will give off its excess energy and perform work in a place more or less distant from that of the absorption of energy. This is the case with certain phosphors, as has been shown recently by N. Riehl[1]. Here, as for example in zinc sulphide, the electron, raised to a higher level by a collision with an α-particle, can travel relatively long distances and will fall back to a lower level, giving up its energy where it meets a copper atom present as an impurity. Thus the absorption and emission of energy will proceed independently at different places.

The problem is whether this state of matter, that is, common energy-levels, exists also in living systems. If it does, it cannot fail to influence profoundly our biological thinking and open new approaches to research and understanding. Protein molecules are systems built up of a great number of atoms, closely packed with great regularity. So theoretically the possibility exists that within these molecules analogous conditions prevail to those in crystals.

The first indication of the existence of such common energy-levels was given by the study of photosynthesis. Emerson and Arnold[2] found that 2,500 chlorophyll molecules form one functional unit. Warburg and Negelein[3] showed that four quanta are necessary for the reduction of one

* Substance of the Korányi Memorial Lecture, given in Budapest on March 21, 1941.

carbon dioxide molecule. There are observations to indicate that these four quanta must reach the carbon dioxide molecule simultaneously. Gaffron and Wohl[4] calculated how many chlorophyll molecules must interact to absorb four quanta simultaneously at the weakest optimal illumination. Their calculation showed that only one thousand molecules are capable of doing this. These observations indicate that the electrons, raised to a higher energy-level by the absorbed light, can move and transport their energy freely through the system of chlorophyll molecules.

Kubowitz and Haas[5] have measured the inactivation spectrum of urease, and P. Jordan[6] has pointed out that their results are in agreement with the idea that common energy-levels exist within this protein molecule. At present, K. Laki and M. Gerendás are engaged in my laboratory in the study of the inactivation spectrum of fumarase, crystallized by Laki. Their results also indicate that the energy absorbed may leave the place of its absorption and cause a break of links at a different place, thus travelling to some distance through the molecule. (If common energy-levels are present in native protein molecules, this cannot fail to contribute to the stability of the molecule and influence its immunological behaviour.)

The more interesting question, however, is not whether common energy-levels exist within one molecule; but whether protein molecules can join into more extended systems with common energy-levels. It would be difficult to picture such a continuum built up of globular protein molecules, and protein molecules have hitherto, with rare exceptions, been found to be globular. However, last year Banga and I[7] found that the proteins building up the solid structure of the cell are fibrous, and that these fibrous molecules, as shown by their strong thixotropy, are interconnected by intermolecular forces. Chloroplasts also contain fibrous proteins.

This finding allows us to suppose tentatively that a greater number of molecules may join to form such energy continua, along which energy, namely, excited electrons, may travel a certain distance. The study of gene mutation, induced by X-rays and ultra-violet light, also indicates such a possibility.

It cannot be expected that any single observation will definitely solve this problem. Only the accumulation of a great mass of data will answer these questions. But even at this early stage we are justified in reconsidering the biological problems in the light of these possibilities.

My own biochemical research of two decades has yielded one or another insignificant result—the isolation of this or that—but whenever I was faced with a fundamental problem, I failed. When these problems are reconsidered in the light of common energy-levels an easy explanation offers itself. I will enumerate a few of these problems, starting with one which arose lately in collaboration with Banga[7].

The contractile element in muscle is myosine, a protein built up of fibrous molecules. These molecules are arranged in small, primitive bundles. A great number of such primitive bundles forms one microscopic fibril. The energy of muscular contraction is derived from the splitting of adenosine triphosphate. The adenosinetriphosphatase activity is bound up with myosine, but our measurements indicate that only a very small fraction of myosine molecules can be endowed with such activity. The problem is, how the energy liberated by a molecule can be communicated to a great number of similar molecules. The common energy-levels give an easy answer.

Another problem that troubled me for many years was why the enzymes involved in oxidation and fermentation can be separated so sharply into soluble and insoluble ones. The enzymes involved in lactic fermentation of muscle are soluble, while the enzymes involved in oxidation are insoluble, that is, bound to the insoluble fibrous proteins of the cell. This difference can be explained if we suppose that the latter are part of a system with common energy-levels. In lactic fermentation no such common levels are necessary, for the single enzymes do not interact but react in series with soluble molecules.

Still another problem, closely connected with the former, is how the enzymes of oxidation interact. In part of the oxidation system electrons wander directly from enzyme to enzyme. The enzymes, being insoluble, have no free molecular motion and must be arranged so that their small reactive groups are at atomic distances. It is possible to arrange two large protein molecules in such a way, but it is geometrically impossible so to arrange a whole series. Even if we could devise such an arrangement, it would still be incomprehensible how the energy liberated by the passing of an electron from one substance to the other, for example, from one iron atom to the other, could do anything useful. All this can be understood if we suppose that the single catalysts are connected with different, distinct energy-levels and that the electrons do not pass directly from one substance to the other but travel within the corresponding energy band, and can fall to a lower level and give off energy only at a place where they can do work (for example, a synthesis) analogous to the zinc sulphide phosphors of Riehl. If the cell and with it the energy-levels are disturbed in some way, we can expect the electrons to fall freely to lower levels at any place. This might explain why cata-

bolic processes prevail over anabolic ones in damaged tissues (and cancer ?), why certain oxidations (catecholoxidase) are activated by damage, why chloroplasts do not build up carbohydrates, and why viruses do not multiply outside the cell.

One of my difficulties with protein chemistry was that I could not imagine how such a protein molecule can 'live'. Even the most involved protein structural formula looks 'stupid', if I may say so. If the atomic structure is only the backbone underlying the common energy-levels, the thing becomes more likely. It is equally difficult to understand the great biological activity of certain molecules. R. Kuhn, F. Moewus and D. Jerchel[8]. have shown lately that one single crocin molecule is capable of inducing a sexual change in a whole alga. If the cell forms an energy continuum, any substance, approaching at any point, can upset the whole system, making, so to say, a hole in the continuum.

Then we do not know what a 'cell' really means, or why the kidney, for example, is subdivided into such units. Possibly the cell wall is the border line of the common energy-levels.

Biochemistry is, at present, in a peculiar state. By means of our active substances we can produce the most astounding biological reactions, but we fail wherever a real explanation of molecular mechanisms is wanted. It looks as if some basic fact about life were still missing, without which any real understanding is impossible. It may be that the knowledge of common energy-levels will start a new period in biochemistry, taking this science into the realm of quantum mechanics.

OBITUARIES

Sir David Wilson Barker

SIR DAVID WILSON BARKER, whose death occurred on June 15, was born on October 1, 1858. He was educated in the training-ship H.M.S. *Worcester*, and on leaving in 1873 joined the Blackwall Line and served in sailing-ships of that company for eight years, rising to the rank of chief mate of the *Superb*. Afterwards he joined the Silvertown Telegraph Works Co., and in 1885 was given command of the cable ship *Dacia*, an appointment which he held with that of cable engineer until August 1892.

Captain Barker will best be remembered as captain superintendent of the training-ship H.M.S. *Worcester*, an appointment which he held with much distinction during 1892–1919.

He was a born seaman and natural scientist—he took a very great interest in meteorology and natural history and made a particular study of sea birds and their habits; he was also an enthusiastic photographer and took up colour photography with some success in its early stages of development.

He was much sought after by various societies and associations on whose committees he served; of these may be mentioned the Royal Geographical Society, the Royal Meteorological Society, of which he was president during 1903–5, and the Challenger Society; he was vice-president International Pollok Prize Committee for Saving Life at Sea, 1901, chairman of British Section of Marseilles International Fisheries Exhibition, 1906. In spite of his busy life he also found time to contribute many papers to the Press on subjects connected with the sea. His numerous activities and the services rendered the country in the training of young officers brought its reward when on retiring from official life in 1919 he received the honour of knighthood.

After his retirement, Sir David continued his active life, lecturing and writing and interesting himself in anything connected with the sea; he was one of the vice-presidents of the London Scout Association and at one time commissioner of Sea Scouts for London. In 1922 he undertook a special mission to Gambia at the request of the Colonial Office to advise on the reorganization of the Gambia Marine.

Many old Worcesters and others will regret his passing and will remember with gratitude his helpful advice and kindly interest—nothing gave him greater pleasure than to meet his "old boys".

Mr. H. W. Hilliar, C.B.E.

THE death occurred at Eltham on July 15 of Mr. H. W. Hilliar, formerly a superintending examiner in the Patent Office. After serving for a time as a chemist at the British Uralite Works near Gravesend, Hilliar (who had taken his B.Sc. at London) entered the Patent Office as an assistant examiner in 1906 at a time when the staff had been greatly enlarged to deal with the newly instituted search for novelty of inventions. By 1914 his work had already received special recognition, and when the War broke out he was lent to the Research Department of the Admiralty, where he conducted important investigations upon the effect of depth charges, for which he was made C.B.E.

Returning to the Patent Office he secured rapid promotion to the grades of examiner (1921), senior examiner (1925) and superintending examiner (1932). During most of his service at the Patent Office he was engaged upon the examination of inventions relating to automatic telephones, of which he had a profound knowledge. He compiled the material for a book on this subject, but his health prevented its completion. He also made a deep study of the case law relating to patents, and in his later years as a hearing officer his judgment both on scientific and legal matters was trusted by all.

Hilliar's first-rate analytical power was combined with great patience, courtesy and charm of character, which endeared him to all who knew him, and his retirement in 1937 owing to ill-health was a great loss to the Patent Office.

We regret to announce the following deaths:

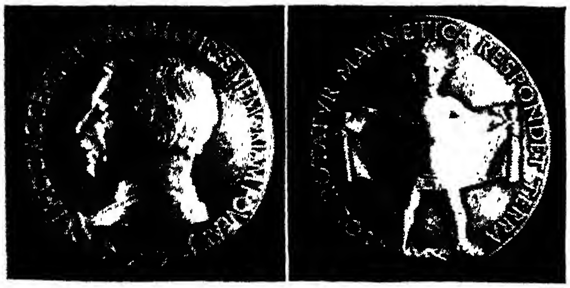
Prof. J. C. Philip, F.R.S., emeritus professor of physical chemistry in the Imperial College of Science and Technology, on August 6, aged sixty-eight.

Prof. A. J. Clark, F.R.S., professor of materia medica in the University of Edinburgh, on July 30, aged fifty-five.

NEWS AND VIEWS

Charles Chree Medal and Address

At the science meeting of the Physical Society on July 25, the Charles Chree Medal and Prize were presented to Prof. Sydney Chapman, who delivered an address, part of which appears on p. 153 of this issue. The circumstances of the foundation were described in the issue of Nature of March 1, p. 261. The Medal, which is a particularly beautiful example of the medallist's art, is the work of the distinguished artist, Mrs. Mary Gillick, and the reverse design most fittingly summarizes and symbolizes the outstanding work of Chree. The Society is to be congratulated on its first award of the Medal.



The Charles Chree Medal

Prof. Chapman's work for the advancement of the science of geomagnetism is both long and distinguished. It began so far back as 1911, when it fell to his lot, on his appointment as chief assistant at the Royal Observatory, Greenwich, to design new instruments and buildings for magnetic observations. His work on the solar and lunar diurnal variation and on magnetic storms is outstanding, and his investigations of the lunar variation have involved the ordering and discussion of an immense mass of material such as would daunt the courage of all save the boldest and most clear-headed investigator. His analysis, which has been made by the aid of methods largely devised by himself, has resulted in a clear formulation of the effect of the sun and moon on terrestrial magnetism, and in a notable increase in our knowledge of the mechanism of the effect. His work on magnetic storms, which has not yet approached a final phase, is of the first importance. The analysis, which has involved very complicated mathematical theory, has resulted in a theory of storms depending on the emission of particles from the sun.

Great Britain and the U.S.S.R.

In reply to the cable of greetings sent by the Royal Society to the Academy of Sciences of the U.S.S.R. (see Nature, August 2, p. 135), Dr. Otto Schmidt, vice-president of the Academy, has sent the following message: "The Academy of Sciences of the U.S.S.R. sends its warmest greetings to the Royal Society, London. Soviet scientists express feelings of deep admiration and friendship to British colleagues who in war conditions pursue courageously their research work, obtaining world achievements in various fields of science and thus successfully opposing the aim of Fascism to destroy all culture. In the struggle for the happy future of humanity, standing hand in hand against the common foe, men of science of Great Britain and the Soviet Union will contribute with all their forces to the triumph of liberty, culture and science over Hitlerite tyranny and obscurantism."

W. H. Hudson Centenary

The centenary of the birth of the British naturalist, W. H. Hudson, occurred on August 4. Hudson was born at Quilmes, near Buenos Aires, and lived on the pampas for thirty-three years, after which he returned to England, where for years he lived in London in poverty, to such an extent that in 1901 he was granted a civil list pension. This he relinquished, however, when belated success reached him. There is no need to relate the titles of Hudson's well-known works which achieved such outstanding popularity. His bird books are probably the best known. A bird sanctuary, with a decoration by

Epstein which has caused considerable controversy, was placed to his memory in Hyde Park, London, in 1925.

In the presence of the British and United States Ambassadors, a bronze plaque was unveiled on August 3 to the memory of Hudson at Berazategui, in the province of Buenos Aires, to commemorate the centenary of the writer's birth. Dr. Fernando Pozzo, president of the Committee of Homage, announced the foundation of the Association of the Friends of Hudson, the chief objects of which will be to acquire the property of Veinte y Cinco Ombues, in Quilmes, the suburb of Buenos Aires where Hudson was born, and to create there a bird sanctuary and a museum of ornithology.

Feeding-stuffs in War-time

THE present position and prospects of home-produced feeding-stuffs in Great Britain have already been reviewed in NATURE (**146**, 251, 362, 712; 1941). Supplementing the papers by Dr. Norman Wright, the Imperial Chemical Industries Research Station at Jealott's Hill has published a bulletin (No. 3) on the same subject, which, as it is written largely in non-technical language, will be especially valuable to farmers, and to others who wish to know the facts before they express opinions on Government policy. Much of the bulletin is devoted to the various ways in which concentrated feeding-stuffs hitherto imported can be replaced by home-grown fodders, and the authors set out to show how the entire present deficiencies can be made good by greatly increased cultivation of oats, barley, peas and beans, by better manuring of grass and fodder crops, by making some six million tons of silage, and treating two million tons of straw with caustic soda to make it into a palatable and digestible carbohydrate feed. Incidentally, they remark that a large proportion of the four million acres of grassland ploughed up in the last two years was land in poor condition and low in fertility, and that without the aid of fertilizers the sanguine expectations of many are likely to be disappointed.

The authors may be somewhat unduly optimistic in their estimates of present potentialities, and also in their assertion that "the belief that there must be a considerable reduction in the number of livestock during the war is the policy of the defeatist". In the War of 1914–18, livestock were slaughtered in Germany and in Britain at a time when both countries were 'all out' for victory, and history is now repeating itself. A useful feature of the bulletin is the comparison of conditions in the year 1875—when British agricultural production was at its height—and in 1938, for it gives some indication of present possibilities. It is recalled that about a century and a half ago, Sir John Sinclair, president of the then Board of Agriculture, warned the country against over-reliance on imported feeding-stuffs, stating that "in times of war our great domestic foe will be our grasslands, which are producing in the most favourable cases only one-fortieth of what we are able to produce under high arable cultivation, which are dependent for their boasted livestock production on vast imports of foreign feeding-stuffs and which, in the case of emergency, will prove one of the weakest links in our national defences". The warning, as is well known, has passed unheeded by those responsible for agricultural policy, with the result that in 1941, as in 1917–18, we are hard put to it to feed our stock and people.

Committee on Agricultural Education

MR. R. S. HUDSON, Minister of Agriculture, has announced that, after consultation with the late President of the Board of Education, he has appointed the following committee to examine the present system of agricultural education, and to make recommendations for improving and developing it after the War: Lord Justice Luxmoore (chairman), Mr. H. Beaumont, M.P., Mr. W. J. Cumber, Mr. Ifor L. Evans, Mr. W. M. Goodenough, Dr. T. Loveday, and Mr. J. M. McClean. Mr. A. R. Whyte, of the Ministry of Agriculture, and Mr. Ronald Ede, secretary of the School of Agriculture, Cambridge, will be joint secretaries to the Committee, and Dr. G. K. Sutherland, of the Board of Education, will act as assessor. Mr. Hudson added that the committee would cover the main work of elementary and secondary school education, and the various types of training required in the different categories of education to include farmers, landowners, bailiffs, farm-workers, land agents, teachers, and technical advisers.

Uses of Wood in Warfare

WOOD wins wars, despite the apparent primacy of metals. This was the subject of an address by Mr. G. W. Trayer of the U.S. Forest Service on June 25 at the midsummer meeting of the American Association for the Advancement of Science. Wood has the further advantage over metals that it can be grown as a renewable crop if good forestry practice is observed, whereas metals are definitely limited and exhaustible resources. Even in aeroplanes, where aluminium and magnesium have replaced the spruce and fabric of the earlier machines, wood is being used again. Plastic-bonded plywood is coming to the rescue of an industry affected by a shortage of light metals. Smaller aeroplanes of this revolutionary new construction, with laminated wooden propellers, have been proved entirely practicable for training purposes.

A modern army's needs for wood are almost beyond counting. They range all the way from lumber for barracks and heavy timber for bridges to wooden poles for holding up camouflage nets and wooden crates for the safe transport of ammunition. Chemical uses for wood are important in warfare. Wood pulp can supply cellulose for nitrating into explosives quite as good as that derived from cotton linters. Black powder, still used to a limited extent in modern war, contains charcoal as an essential ingredient. More important, compressed wood charcoal is now replacing coconut-shell charcoal in the canisters of gas masks.

A Major Cause of Hay-fever

Extraction from ragweed pollen of a colourless, nitrogen-containing chemical believed to be one of the major causes of hay-fever was announced by Prof. Harold A. Abramson and Dr. D. H. Moore of the Columbia University School of Medicine and Dr. H. H. Gettner of Mount Sinai Hospital, at the Wilder D. Bancroft Colloid Symposium held at Cornell University under the auspices of the National Research Council and the American Chemical Society on June 20. The molecular weight of the chemical was found to be "surprisingly low—only 5,000". This small size is significant, it appears, from the explanation that in order to produce hay-fever, pollen must not only be blown into the nose and eyes, but also the molecules causing the symptoms must pass through the mucous membranes into the deeper tissues beneath. "Our study indicates that the ease with which allergic individuals will become sensitized to the contents of pollen grains may depend to a great extent upon the small size of the allergenic molecules which have now been isolated and studied quantitatively by electrophoresis, by ultracentrifugation, and by diffusion experiments for the first time".

Industrial Research Bureau, India

The report of the Industrial Research Bureau of the Government of India for the year 1939–40 (Delhi: Manager of Publications. 1*s.* 9*d.*) refers to the reorganization entailed by the decision to curtail severely plans for expanding the staff of the Bureau and the Government Test House. The Industrial Research Bureau and Research Branch of the Government Test House have now been merged by the formation of the Board of Scientific and Industrial Research and the office of the Director of Scientific and Industrial Research, the first director being Sir Shanti Swarup Bhatnagar. The report on the work of the Industrial Research Council refers to investigations carried out on oils and soaps as well as on the development of the glass industry, and particularly to progress made in the designing and installation of improved glass-melting furnaces. Progress has been made in the survey of deposits of glass-making materials as well as in the survey of the oil-seeds crushing industry.

In regard to the co-ordination of the universities and research institutions in India with the development and extension of industrial research, attempts are being made to obtain the co-operation of the universities in preparing the combined list of industrial researches completed, in progress and proposed to be undertaken in Government laboratories, universities and research institutions in India. Publication of an annual combined list is contemplated. The report on the work of the Industrial Research Bureau also refers to the co-ordination of universities and research institutions. The number of laboratories in India capable of undertaking industrial research work is limited, and after considerable attention had been given to the matter it has been decided to provide funds to be allocated to selected institutions for the payment of grants to workers engaged in research falling within the programmes to be arranged on the recommendations of the Board of Scientific and Industrial Research.

The Indian Lac Research Institute has continued its work on the development of moulding powder compositions containing a considerable percentage of shellac. The Research Branch of the Government Test House has continued its investigations on paints, particularly on accelerated weathering, paint formulæ, fungus growth on paints, and the physical properties of paint films. Work on the factors affecting the properties of dry cells has been continued during the year and some correlation established between the chemical constitution and electrical performance of ores. An automatic cooking machine for dry cells has been designed and constructed in the laboratory. Work on vegetable oils as lubricants has indicated that phenyl-α-naphthylamine, as.-diphenyl-hydrazine, *p*-toluidine and phloroglucinol are the most effective stabilizers for castor oil and rape-seed oil in the presence of iron. A number of blends were prepared for engine tests, and details of these trials are included. Other work has covered the use of vegetable oils as Diesel fuels, building materials, particularly the use of Surkhi as pozzolana.

Trees of the Past

A short interpretation of the fossil herbaria of the rocks by the late Sir Albert Seward (*J. Roy. Hort. Soc.*, 66, Pt. 6, June, 1941) provides a useful epitome of palæobotanical knowledge. The paper deals particularly with trees, and the story commences with *Cercidiphyllum japonicum*, an Eocene fossil species which is still indigenous in China and Japan. Cretaceous strata brought the first geological appearance of the genus Magnolia. Tulip-tree, plane, hazel and oak are present-day trees with stratigraphical antiquity. The maidenhair tree, *Ginkgo biloba*, is one of a group of plants which flourished in the Jurassic and Triassic periods. It is curious that many trees which now only appear in China and Japan were inhabitants of Europe and North America in earlier geological time; west and east seem to have changed places. The Norfolk Island pine, *Araucaria excelsa*, also had a divergent distribution in the past, for fossil leaves, cone scales and seeds were discovered in 1931 from Tertiary sediments in the Kerguelen Archipelago, where now is found only a scanty flora of flowering plants, ferns, mosses and lichens, but no trees.

Wild Flower Society

The 264th issue of the Wild Flower Society Magazine is an enlarged double one covering January–June 1941, an evidence of the Society's decision to carry on during war-time. Many contributors stress the danger of the Women's Institutes' Herb Scheme exterminating rare British plants unless the Government-encouraged collection of wild drug plants is botanically supervised. The chief paper in the issue is the first supplement to Green's "Flora of Liverpool"

which Mr. Eric Hardy has drawn up for the Merseyside Naturalists' Association. Covering botanical vice-counties 58 and 59, it adds new records of a number of plants. The increase of a hermaphrodite form of *Bryonia dioica* on the Lancashire dunes, a new unnamed Œnothera hybrid and the extinction of *Rumex cuneifolius* (first recorded in Britain from west Cheshire, 1913) are also noted.

Biological Investigations at Palao

THE first part of the second volume of the "Studies of the Palao Biological Station" contains seven reports relating to corals, detailed descriptions of four species of Pheretima (Oligochæta) and an examination by Y. Haneda of the luminescence of shore fishes of the genus Leiognathus. In these latter the luminous body is in the form of a ring surrounding the œsophagus where it enters the body cavity. The light in the eleven species examined passes through the muscles, which are milky white and translucent. The gland has two openings from the œsophagus. Through these, luminous cocci enter and settle down, the response to outer stimuli being rapid.

Three reports deal with the biochemistry of corals, and Motoda compares the conditions in the open sea with those in the lagoon; these are preliminary reports. Motoda also studies the growth-rate of a massive coral (Goniastrea) by the multiplication of its polyps. It is a coral of the reef flat and thus subjected to tidal waters, which are studied in respect to temperature, salinity, oxygen content, *p*H and exposure to air. The oxygen production by ten polyps under varied conditions of light and depth, this due to their symbiotic algæ, gives 0·22–0·14 per hour at a depth of 6 cm. in clear weather, while under thick clouds 0·08 c.c. is consumed. Direct exposure to the sun's rays in air is successfully resisted for two hours, but nearly all polyps are killed after six hours. The growth-rate decreases with age, but most colonies died before the second count. It had previously been suggested that this decrease is correlated with reproductive activities, but this is not considered. Finally, Abe's work on Fungia is interesting as dealing with the effect of sediments.

School Hygiene in São Paulo

THE School Health Service of São Paulo, Brazil, claims to be one of the oldest, if not the oldest, child welfare institution. By a decree of December 28, 1938, the service has been reorganized, with the enlargement of existing facilities and the creation of other services including those of mental hygiene and child guidance clinic, allergy clinic, endocrinology and nutrition clinic, dermatology and syphilis clinic, educational puericulture for students of normal and professional schools, X-ray and laboratory services, etc. During the first half of 1939 the Service, which is under the Department of Education, attended 94,108 children, made 2,286 health examinations at headquarters and 42 at home, 1,426 vaccinations at headquarters, attended 39,144 children in the Largo de Arouche School Polytechnic, 4,216 in the eye service, 5,369 in the otorhinolaryngology service, 388 in the dermatology and syphilis clinic and 3,819 in the X-ray clinic. In the School Groups, 26,276 children were examined.

Vital Statistics in New Zealand

ACCORDING to the annual report of the Royal New Zealand Society for the Health of Women and Children founded by the late Sir Truby King, the birth-rate of the Dominion in 1939 (excluding Maoris) was 18·73 per 1,000, the highest recorded since 1930. The maternal mortality-rate, excluding septic abortion, was 2·95, and the infantile mortality-rate 3·14 per 1,000 births, almost the lowest ever recorded. The death-rate during the first month of life was 21·8, an improvement on the figure for recent years. The Society has six infants' hospitals in various parts of New Zealand, and the 138 Plunket nurses in its service saw 22,000 new cases during the most recent year and paid 170,000 visits to homes.

The National Trust

THE report of the National Trust for the year 1940–41 shows the unique position attained by this society devoted to the preservation of places of historic interest or natural beauty. Not only are bequests of land coming to the Trust upon an increasing scale, but the recent Country Houses Scheme has received important support in the transfer of the beautiful Blickling Hall, Norfolk, and its large estate, to the control of the National Trust. In the terms of Lord Lothian's will the freehold is vested in the Trust on the condition of preserving the amenities, and with the request that in the choice of tenant preference shall be given to descendants of the donor, subject to facilities for the access of the public. Death duties on large estates are now on such a destructive scale that the preservation of England's noble mansions, their period furniture, and surrounding parks can only be ensured by their transfer to a permanent society such as the National Trust.

Fire Risks in Railway Trains

THE report which Colonel A. C. Trench has presented to the Ministry of War Transport on the fire in which six schoolboys lost their lives and which destroyed three coaches of an express train on the L. and N.E. Railway on April 28 should not disturb faith in the general safety of railway travel in Great Britain. It is unfortunate, as is pointed out in *Engineering* of July 11, that, in the interests of economy, the reports of inquiries into the causes of railway accidents are no longer being published and circulated in the usual manner. This is doubly regrettable, for the account of the tests carried out by Colonel Trench, in spite of war conditions, is good evidence of the morale of the country.

The train in question was travelling at about 55 miles an hour when the fire began; it was stopped in about a mile and a quarter, by which time the fire had taken a firm hold on one coach. Colonel Trench refers in his conclusions to the locking of doors of unoccupied vans and of gangway and corridor doors. He also suggests that the wadding

and the outer rexine covering on the backs of the railway seats, where the fire in this case began, might be omitted. It is evident that the main lessons of this fire require to be studied by the travelling public in general rather than by the railway companies or their employees. The carelessness habitually displayed by many passengers in the disposal of matches and cigarette ends is quite inexcusable; nevertheless, the provision of more and larger 'ash trays' might be considered.

Making Light for To-morrow

THE *Electrician* of July 4 quotes Mr. S. G. Hibben, director of applied lighting to the Westinghouse Lamp Division, as attributing most of the very rapid progress being made in developing illuminants to the influence of the large 'fairs' recently held in the United States. Each exhibition has been identified with some new and often radical means of producing light. The Panama-Pacific Exposition of 1915 ushered in the use of tungsten filament lamps of large wattage for exterior floodlighting, and coloured beams from carbon-arc searchlights. In 1926 the Philadelphia Sesqui-Centennial Exposition presented colour-coated incandescent filament lamps with spirally coiled filaments surrounded by inert nitrogen and argon, in sizes down to and including the commercial 60-w. lamp. High voltage (10,000 volt range) neon and mercury tubing for architectural decoration were also used. The high-intensity mercury vapour lamps were publicly introduced into the United States at the Chicago Century of Progress Exposition in 1933.

Noteworthy above all others, the New York World's Fair of 1939–40 introduced in that country the radically new and efficient fluorescent lamps. In addition, there were also introduced new sizes of mercury vapour lamps for the illumination of foliage, the production of short-wave visible colours for underwater fountain lighting, new projector lamps, and the popularly termed 'black-light' lamps or long-wave ultra-violet illuminants. The latter of these gave a wide variety of fluorescent effects. Whilst attention is naturally focused on the new or unusual illuminants, it has to be remembered that the familiar incandescent lamp is, and for many years to come will be, the basic, most commonly used lamp for work requiring light primarily. More precise manufacturing methods and lower costs now give the purchaser two and a half times as much light for the same money, as compared with 1928.

Seismological Data from India

VALUABLE seismological data is contained in the *Seismological Bulletin* of the Government of India Meteorological Department for the period January–March 1940, published under the direction of Dr. C. W. B. Normand. Interpretations of the seismograms obtained at the observatories at Agra, Bombay, Calcutta, Colombo, Dehra Dun, Hyderabad and Kodaikanal are given in considerable detail, and it is pleasing to note that J. H. Sil at Poona has again collected non-instrumental reports from voluntary observers. At the Upper Air Observatory at Agra, ninety-four earthquakes and tremors were recorded instrumentally during the quarter, and in each case there are given the type of wave with its arrival time, occasionally its period and amplitude, together with the estimated epicentral distance and depth of focus. The deepest focus shock recorded was apparently one approximately 200 km. deep estimated by the Brunner Chart, on March 28, at an estimated epicentral distance of 4,135 km. The other observatory reports are along similar lines. Fifteen earthquakes were recorded by voluntary observers. Three of these reached intensity 7 on the Rossi-Forel scale. These were at Srinagar on January 26, Gauhati on February 13 and Drosh on March 19, the latter also being recorded with lesser intensities at Kabul, Peshawar and Srinagar.

Announcements

THE Bisset-Hawkins Medal of the Royal College of Physicians has been awarded to Sir Frederick Menzies for his work as chief medical officer of the London County Council, and the Baly Medal has been awarded to Prof. Edgar Allen, of Yale University, for his work on œstrogens.

PROF. JEAN PERRIN, formerly professor of physical chemistry in the University of Paris, has been invited to become visiting lecturer at Wilson College, Chambersburg, U.S.A., during the academic year 1941–42.

THE South African Institute for Medical Research in Johannesburg is about to undertake the manufacture of yellow fever vaccine under the directions of Dr. G. M. Findlay of the Wellcome Research Institute of London.

THE American Society for X-Ray and Electron Diffraction, plans for which were announced in *Science* of May 23, starts its existence with a charter membership of 124. The officers elected for 1941 are: *President*, Dr. M. L. Huggins, of the Eastman Kodak Company; *Vice-President*, Prof. B. E. Warren, of the Massachusetts Institute of Technology; *Secretary-Treasurer*, Dr. George Tunell, of the Geophysical Laboratory, Washington, D.C.

THE British Association's Division for the Social and International Relations of Science is arranging a meeting to be held, if circumstances allow, on September 26, 27 and 28. Various subjects under the general heading of "Science and World Order" will be dealt with. The first day's session will take place, by kind permission, in the theatre of the Royal Institution, Albemarle Street, London, and those of the second and third days, it is hoped, at the Rothamsted Experimental Station, Harpenden.

DR. KENNETH M. SMITH writes: "In a recent review entitled 'Insects and Plant Diseases' (NATURE, July 19, p. 65), through an error in proof-reading, it was made to appear that 1801 was the date of the first discovery of bacteria as a cause of plant disease. This should, of course, be 1881, eleven years before the first demonstration of a virus by Iwanowsky in 1892."

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Structure of Cobalt

POWDER photographs of hexagonal cobalt do not always have consistently sharp lines, and the variation of sharpness is not explainable by internal strains or by small particles of unusual shapes. This may be seen from the following table of visual estimates of the breadths of the various lines on a photograph taken with nickel $K\alpha$ radiation.

$h\ k\ i\ l$	Description	$h\ k\ i\ l$	Description
$1\ 0\ \bar{1}\ 0$	sharp	$1\ 1\ \bar{2}\ 2$	sharp
$0\ 0\ 0\ 2$	sharp	$2\ 0\ \bar{2}\ 1$	broad
$1\ 0\ \bar{1}\ 1$	broad	$0\ 0\ 0\ 4$	sharp
$1\ 0\ \bar{1}\ 2$	broad	$2\ 0\ \bar{2}\ 2$	very broad
$1\ 1\ \bar{2}\ 0$	sharp	$1\ 0\ \bar{1}\ 4$	very broad—almost invisible
$1\ 0\ \bar{1}\ 3$	very broad		
$2\ 0\ 2\ 0$	sharp	$2\ 0\ \bar{2}\ 3$	very broad

We have examined the problem by means of powder and oscillation photographs and have found that the following theory is capable of explaining the observations.

It is well known that the close-packed structures can be derived from three types of close-packed planes of atoms; the co-ordinates with respect to the two hexagonal axes of the atoms in each plane are:

$$(0, 0) \ldots A\,; \quad (1/3, 2/3) \ldots B\,; \quad (2/3, 1/3) \ldots C.$$

In a normal hexagonal structure only two of these types are used, thus: *ABABAB* . . ., but it is easy to see that faults may arise and that the sequence may change to *CBCBCB* . . ., or to *ACACAC* . . . If such faults occur frequently the structure will be irregular, but certain sets of planes, such as the (0001)'s, will obviously remain perfect. In general, all sets of planes with $(h\text{-}k)/3$ integral will be perfect, and this is in accordance with the observations in the accompanying table.

From the broadening of the lines an estimate of the degree of imperfection can be made, and it was found that in the specimen which was examined the probability of a mistake occurring was as high as 1/10.

The same kind of theory is applicable to other problems, notably the broadening of the superlattice lines in $AuCu_3$ due to the presence of small 'antiphase domains' in single crystals.

A more detailed account of the work on cobalt will be published elsewhere.

Wave Form of Atmospherics

SEVERAL investigators[1,2,3] have shown that an atmospheric often has a characteristic 'slow tail' of a few milliseconds' duration, in addition to the customary wave train of a few cycles of frequency about 10^4 cycles per second. The latter has been associated with the return stroke of the lightning discharge, and precision has recently been given[4] to this suggestion by the calculation of the amplitude and duration of one cycle of this wave from the characteristics of the return stroke, the remainder of the wave being presumably due to reflexions from the ionosphere[5].

As to the 'slow tail', Appleton and Chapman[2] have suggested that this is connected in some way with the slow *c* portion of the lightning discharge. A study of the electrostatic field changes caused by near strokes recorded by these authors[2], however, suggests that the 'slow tail' is the result of the radiation due to the destruction of electric moment during both the *a* and the *c* portions of heavy strokes, an explanation which is supported by the occurrence of the high-frequency radiation due to the *b* portion within the 'slow tail', observed at relatively near distances[1]. The durations involved are obviously of the right order, being in each case a few milliseconds. As to the amplitude, my theory[6] of the increasing corona current as the leader stroke approaches the earth yields, from the relation

$$\varepsilon_r = \frac{1}{c^2 r_{\_}} \, \frac{d^2 M}{dt^2},$$

a final value of the order of 10 or 20 millivolts/metre for the radiation field due to the *a* portion at 100 km., assuming that the corona current increases as the square of the voltage. During the *c* portion a charge of the order of 10 coulombs often flows from cloud to earth in a time of the order of 3 milliseconds[4]. If this charge is initially at a height of 2·5 km., and if its electric moment is destroyed exponentially, which the aforementioned records[2] show to be approximately the case, then the above relation yields a crest value for ε_r at 100 km. of the order of 70 mv./m. These values compare well with the observed value of 125 mv./m. at 100 km.[1].

It would thus appear that the 'slow tail' represents the radiation resulting from the destruction of the electric moment during the *a* and *c* portions of a lightning stroke.

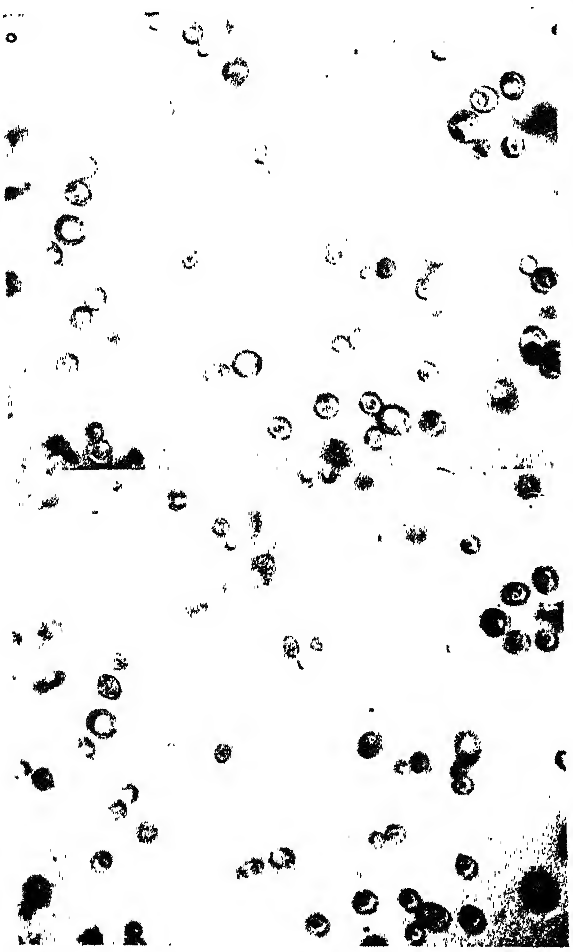
Increased Ultra-violet Absorption of Cells Following Irradiation with Ultra-violet Light*

PREVIOUS investigations[1] have indicated that one of the responses of cells to various injurious agents (for example, lethal ultra-violet light and X-rays) is the release into the intercellular fluids of nucleic acid-like proliferation-promoting factors ('intercellular wound hormones'). Considerable evidence indicates that these active factors are produced in the living cell as a response to injury[2]. The present investigations were aimed at determining by direct observation of living cells whether there is an actual increase in cellular nucleic acids, purines or pyrimidines, during the course of injury. For this purpose, ultra-violet photomicrography was employed, following techniques well established by Caspersson[3].



TWO ULTRA-VIOLET PHOTOMICROGRAPHS OF *S. cerevisiæ* FROM A TYPICAL SERIES, SHOWING INCREASED ABSORPTION OF ULTRA-VIOLET FOLLOWING IRRADIATION WITH SUB-LETHAL DOSES ON THE MICROSCOPE STAGES AT $\lambda = 2800$ A. ABOVE, BEGINNING OF EXPERIMENT; BELOW, SAME FIELD ½ HR. LATER.

A Zeiss quartz microscope was used, with 2·5-mm. glycerine immersion objective, 10× eyepiece, and quartz double monochromator illuminator. A cadmium spark light source was used for $\lambda = 2800$ A. and a General Electric type *H*-3 high-pressure mercury arc for $\lambda = 2537$ A. A hole cut in the outer glass jacket of the mercury arc permitted passage of the ultra-violet. The organism was *S. cerevisiæ* (Fleischmann bakers' yeast). This was suspended in isotonic salt solution or water, sealed under a quartz coverslip on a quartz slide, and irradiated continuously on the microscope stage with the lethal radiation employed as the microscope illuminant. Photomicrographs were taken at the beginning of the experiment, and at fifteen-minute intervals during the course of irradiation.

The plates showed a progressive increase in the ultra-violet absorption of the cells during irradiation. Since the wave-lengths employed were in the range highly absorbed by purines and pyrimidines[4], one can interpret the results as indicating a production by the injured cells of nucleic acid-like materials. This is consistent with the previous results[2] indicating that proliferation-promoting intercellular hormones are produced in living, injured cells as a response to injury. Two photomicrographs from a typical series are shown in the figure.

In Mitchell's studies of the possible relationship of nucleic acids to the radiosensitivity of tumours, he found an increase in the ultra-violet absorption near 2600 A. of carcinoma tissue and normal epithelium irradiated with X-rays or gamma rays *in vivo* and afterwards examined in section by ultra-violet photomicrography. He interpreted the increased absorption as due to purines or pyrimidines, and not to thymonucleic acid (negative Feulgen reaction). From *in vitro* experiments, he concluded that the effect was not due to direct photochemical changes in the cytoplasm. The supposed purine or pyrimidine nature of the absorbing materials, their apparent production as a result of the effects of lethal agents (X-rays and gamma rays), and their evident formation by living, injured cells rather than as a direct photochemical effect, all suggest that Mitchell was observing the production of the proliferation-promoting factors we have been investigating. If this is true, it points to the advisability of a careful study to determine whether the production of proliferation-promoting factors by injured cells is an initial result of the irradiation of tumours by X-rays and gamma rays. The release of such factors into the tumour mass and surrounding tissues might conceivably play an important part in the variability of the response of tumours to irradiation.

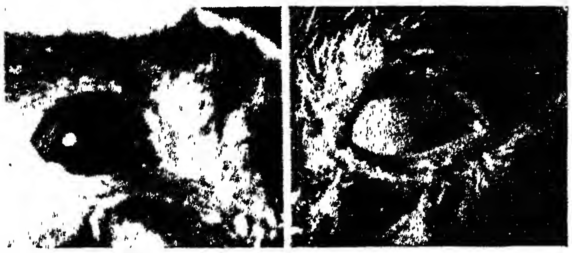
Local Treatment of Experimental Pyocyaneus Ulcers of the Cornea with Albucid Soluble

JOY[1] recently demonstrated that the development of experimentally produced ulcers of the cornea in rabbits could be favourably influenced by the parenteral administration of sodium sulphapyridine. It has also been shown that sulphanilamide penetrates freely through the cornea[2,3].

We have investigated the effect of local application of a water-soluble sulphonamide on experimental ulcers in seventeen rabbits. In each animal a definite area in both eyes was denuded of epithelium by means of a discission needle. Great precautions were taken to ensure that the lesions were equal in both eyes. A 24-hour culture of *B. pyocyaneus* (kindly supplied to us by Dr. Oag, of the Department of Bacteriology of the University of Edinburgh) was then applied to these denuded areas by means of a metal loop; the same strain of *B. pyocyaneus* was used throughout all the experiments.



(*a*) (*b*)

Fig. 1.

SHOWING THE CONDITION OF THE CORNEA IN THE TREATED (*a*) AND CONTROL (*b*) EYES OF A RABBIT ON THE THIRD DAY AFTER THE PRODUCTION OF THE LESION.

Treated eye: cornea healed and showing only a small superficial scar situated at the centre of the cornea immediately adjacent to the light-reflex which is overlying the margin of the pupil. Control eye: severe abscess involving half the cornea.

One hour after the application of the culture several drops of a 30 per cent solution of albucid soluble (which forms a neutral solution) were applied to the cornea of one eye in each animal, the other eye being used as a control and receiving several drops of saline. This treatment was continued four times a day until the lesions were quiescent.

In the majority of the 'control' eyes extensive ulceration occurred and a complete or partial 'ring abscess' developed, the end result being either perforation or gross scarring of the cornea with extensive pannus formation. In some animals, however, the ulceration was limited to the site of scarification, and the resultant scar was very little larger than the original lesion.

In every animal the lesion in the control eye was more severe than that of the treated eye. In eleven animals the difference was very marked (see accompanying illustration), in four animals the difference was less marked, but the treated eye was still definitely better than the control, while in two rabbits the treated eye was only slightly better.

The extent to which ulceration or abscess formation occurred in the cornea is summarized in Table 1.

It is noteworthy that a partial or complete ring abscess developed in twelve of the control and in only three of the treated eyes. Hypopyon was observed in five of the control eyes and in only one of the treated eyes.

TABLE 1.

	No ulceration.	Ulceration present but not extensive.	Extensive ulceration, abscess formation, or necrosis, with or without perforation.
Control eyes	0	4	13
Treated eyes	11	4	2

Conjunctivitis did not play a prominent part in the lesions produced, but again the treated eyes were on the whole very definitely better than the controls, and in no case was the treated eye worse than the control eye of the same animal. The results are shown in Table 2.

TABLE 2

CONJUNCTIVITIS

	Nil	Slight	Moderate	Severe
Control eyes	0	10	6	1
Treated eyes	10	6	0	1

The expenses of this investigation have been defrayed by the W. H. Ross Foundation for the Prevention of Blindness. We are greatly indebted to Mr. Edwards, of Messrs. Schering, London, for the supply of ampoules of 30 per cent solution of albucid soluble.

Sulphanilylbenzamide in the Chemotherapy of Bacillary Dysentery

SULPHANILYLGUANIDINE, first described in 1938[1], was recently introduced by Marshall and his colleagues[2] in the treatment of bacterial infections of the intestinal tract. A subsequent report[3] dealt with the successful trials of this compound in acute bacillary dysentery due to Flexner and Sonne types in children. The use of the drug is based on its potent antibacterial properties, its solubility in water and its poor absorption from the gut. We have re-examined a large number of drugs of the sulphanilamide and sulphone classes having similar characteristics and have found two soluble compounds, 4: 4'-*bis*-γ-phenyl-*n*-propylaminodiphenylsulphone tetrasodium sulphonate and sulphanilylbenzamide to be more effective *in vitro* than sulphanilylguanidine. However, when these compounds were incorporated in the diet of mice, only sulphanilylbenzamide was as efficient as sulphanilylguanidine in its antibacterial action on the coliform organisms of the gut. When fed to rabbits by stomach tube, sulphanilylbenzamide is poorly absorbed, but it is absorbed to the extent of one and a half times that of sulphanilylguanidine.

Our *in vitro* tests compared the antibacterial activity of constant drug concentrations in a stock broth against graded inocula of selected intestinal

pathogens. The range used included strains of Sonne, Flexner, Newcastle, Shiga, coli, typhoid and cholera. We have always found Sonne strains to be the most resistant to sulphanilylguanidine and Shiga and typhoid strains somewhat resistant, while sulphanilylbenzamide has proved highly potent in all types. The mouse test referred to above is one suggested by Marshall[2]. It is based on the reduction in the concentration of the lactose-fermenting organisms in the fresh stools of mice fed on a diet containing 2 per cent of the drugs. Fresh fæces are made into an emulsion containing approximately 50 mgm. in 5 ml. of broth and graded dilutions made on desoxycholate agar plates. The lactose-fermenting organisms are counted after twenty-four hours. Under these conditions sulphanilylbenzamide is as efficient as sulphanilylguanidine.

Whether the promising *in vitro* results, especially against Sonne, Shiga and typhoid types, are reproducible in man will in turn depend on whether the more rapid absorption of sulphanilylbenzamide from the gut is significant. Arrangements for such a clinical trial are being made.

It is hoped to publish a detailed account of this work elsewhere.

We have to thank Mr. T. Dewing of the Wellcome Chemical Works, Dartford, for kindly supplying sulphanilylbenzamide and Mr. W. H. Gray of the Wellcome Chemical Research Laboratories for kindly supplying 4 : 4'-*bis*-γ-phenyl-*n*-propylaminodiphenylsulphone tetrasodium sulphonate.

Latero-sensory Canals and Dermal Bones

J. A. MOY-THOMAS[1] has recently made important observations on the developmental relationship between the frontal bones and the supraorbital latero-sensory canal in Salmo, and clearly considers that his experiments go far to destroy the whole basis of the homologization of dermal bones in fishes by reference to the latero-sensory system. His results are quite in harmony with, for example, Kindred's embryological study of Amiurus[2], and no doubt somewhat similar conditions occur widely in teleosts, where the dermal bones of the skull-roof, particularly the frontals, play an important part in the mechanical structure of the cranium.

It is true that some workers have carried the use of the latero-sensory too far, especially where originally enclosed canals show a phylogenetic 'degeneration' to pit-lines, and I have several times[3,4,5,6] noted necessary modifications to some of these rigid schemes. Nevertheless, in certain primitive fossil forms, and in the development of Amia (Pehrson[7]), there is abundant and convincing morphological evidence of a close developmental connexion between certain dermal bones and the latero-sensory system (excluding pit-lines). In the most primitive known Actinopterygii, Crossopterygii and Dipnoi the adult dermal skull-roof consisted of bony plates, occupying the whole thickness of the corium, but having no part in the mechanical construction of the cranium; somewhat similar conditions still hold in Amia. But in most teleosts (Actinopterygii) and in all but the most primitive tetrapods (from Crossopterygii), several of the dermal bones have new functions as mechanically important cranial elements, and may become deep-seated. It is precisely in these forms that the importance of latero-sensory canals as 'markers' of dermal bones is so greatly reduced. I am therefore unable to accept all Moy-Thomas's conclusions. His experiments should be repeated on Amia before such deductions can be drawn with confidence.

Moy-Thomas's findings are not unexpected. The early Crossopterygii, and probably the earliest tetrapods, are generally considered to show a close relationship between some of the dermal bones and latero-sensory canals; but in higher tetrapods latero-sensory canals fail to develop, and dermal bones such as the frontals form part of the mechanical structure of the skull. What seems to have been, in primitive forms, a simple 'secondary organizer' relationship involving early formed latero-sensory structures and certain later developed dermal bones, is replaced in tetrapods by apparently more complicated processes, in which the more integrated architecture of the cranium is clearly an important factor. The same may prove to be true of many Teleostei, and it seems likely that a programme of experiments like those of Moy-Thomas, applied to a large series of teleosts and to Amia, Lepidosteus and sturgeons, would provide valuable evidence in the important problem of the changes in organizer-reactions involved in the gradual modification of phylogenetically archaic structures to meet new needs.

Function of the Ventral Tube in *Onychiurus armatus* (Collembola)

VERY little is known about the function of the ventral tube of Collembola. Until recently it has been regarded as an adhesive organ, but the observations of W. M. Davies[1] suggest that in *Sminthurus viridis* (Linn.) at least, it may be used for cleansing the body and as a means of transferring drops of water from the surface of the body to the mouth where they are then absorbed. In connexion with this, Davies has suggested that 'free water' is essential for the survival of this species, even in a water-saturated atmosphere.

It is interesting, therefore, to record some results obtained with the soil-living Collembola, *Onychiurus armatus* (Tullb) under various culture conditions.

Onychiurus armatus has been maintained on Mucor cultures on agar media in Petri dishes where it moved freely over the vertical and horizontal surfaces without using the ventral tube vesicles. When placed on vital stains in various humidities the stain was

absorbed through the ventral tube, and the lower the humidity the more rapidly was the stain taken up. The distal joints of, in particular, the hind limbs, which were immersed under these conditions, also became stained.

On agar blocks, where only the tips of the legs and the ventral tube vesicles were in continuous contact with the agar surface, in a low humidity the animals survived for a much longer period than when in the same humidity but on a dry surface. The extrusion of the vesicles was only sufficient to reach the surface of the agar and no action of the vesicles comparable with that observed in *Sminthurus viridis* by Davies, has been seen. Puncturing the vesicles had the effect of reducing greatly the length of life except in a saturated atmosphere.

Onychiurus armatus apparently has no mechanism for preventing water loss, and the ventral tube vesicles seem to be the primary water-absorbing organs.

Relative Growth in the Individual

WITH regard to A. E. Needham's communication[1] stressing the desirability of obtaining relative growth data on individuals as distinct from contemporaneous data obtained in populations, we would like to point out that such data relating to guinea pigs were published by us some time ago[2]. We then demonstrated the isometry of teat-length against body-length in the young male guinea pig and the occurrence of 'simple' allometry of the teat under androgenic stimulation. In these experiments data for groups of comparable individuals were averaged.

More recently[3] we have published a preliminary account of teat-growth data obtained on individual goats, showing that in the young female a phase of teat isometry is succeeded by a phase of 'simple' positive allometry; the constant α was found to vary among individuals. A more detailed account of these last observations is in the press[4].

Miocene Deposits in Kenya

IN 1935 I examined the Miocene deposits of Kavirondo, Kenya, but as publication of results (already overdue) seems likely to be further delayed, I should be grateful for an opportunity to summarize the more important results with reference to misconceptions which have arisen about the age of the formation and its fauna.

The deposits are exposed in three main areas: Rusinga, an island on the edge of Lake Victoria, Karungu, originally described by Oswald[1], and Koru, farther east. The rocks are largely volcanic in origin, and in each case are associated with a major volcanic centre. On Rusinga the lower beds are fossiliferous clays with thin sandstones containing a small proportion of tuffaceous material; these are succeeded by tuffs with an intercalation of red clays and thin limestones, and the tuffs overlain in turn by agglomerate and nephelinite lava. The tuffs and agglomerates thicken rapidly towards the south-west, indicating as source the Gwasi volcanic centre of South Kavirondo. Adjacent islands provide confirmatory evidence of this. Karungu lies on the southern fringe of the same volcanic mass, and the fossiliferous beds there are correlated with the lowest beds of Rusinga. Koru shows a succession broadly similar to Rusinga, but red clays with limestones in the middle part provide the main fossiliferous horizon.

Bailey Willis[2] has argued that the Karungu deposits are fluviatile Pliocene, containing occasional derived Miocene fossils, and Broom[3] has recently queried the Miocene age of Proconsul from Koru on systematic grounds. It is therefore necessary to confirm, first, that the fossiliferous part of the formation is definitely lacustrine, secondly, that the fossils are truly autochthonous, being in some cases articulated and in most cases quite unrolled, and thirdly, that Dr. A. T. Hopwood and D. G. MacInnes, who have separately worked on the fauna, are quite satisfied that it is of Lower Miocene date.

Independent evidence indicating considerable age is provided by the later history of the deposits. On Rusinga the beds show strong deformation, including isoclinal folding and thrusting with production of phacoidal structures, which it is exceedingly difficult to explain other than by lateral compression (in this connexion Willis's theory of an expanding disk beneath Lake Victoria as the force which produced the Rift Valleys should be remembered). In particular, it may be emphasized that the phenomena are quite distinct from those of slumping, well-developed in neighbouring Pleistocene beds. Afterwards the deposits were intruded by igneous dykes, and in the west extensively eroded with relation to a base level beneath the present lake before the formation of high-level raised beaches in the Lower and Middle Pleistocene. Between deposition of the fossiliferous beds and the Lower Pleistocene, therefore, accumulation of up to 500 ft. of tuffs and agglomerates, extrusion of lava, disturbance of the beds, dyke intrusion and extensive erosion successively occurred, which supports the palæontological evidence in suggesting a date at least as early as Miocene.

This early disturbance of the African peneplain, previously doubted by some authorities, is further illustrated by the discovery of phonolite-covered Lower Miocene beds in a valley cut in the gneiss of the northern scarp of the Kavirondo Rift, which must, accordingly, be of pre-Miocene age.

THE ONTARIO RESEARCH FOUNDATION

THE report of the Ontario Research Foundation for the year 1940 includes the Director's report together with the financial statment and a full list of publications to December 31, 1940. The Director's report refers to the new problems created for those engaged in agriculture, particularly to work concerned with remedying the slow depletion of the soil. The Foundation is studying areas which show evidence of trace-element depletion and also characteristic deficiency diseases, such as boron deficiency in the apple, sugar beet and turnip, copper deficiency in the onion and manganese deficiency in oats. A survey of land values in rural Ontario and their relation to soil, climate and economic factors has been commenced. The work on mastitis in cows has continued throughout the year and evidence has been secured proving that the leucocytes present in milk can destroy the characteristic bacteria which are associated with mastitis. A study of the pathological changes in the udder of the cow caused by tuberculosis and other diseases has been commenced.

In the late autumn the pathological and bacteriological staff were fully occupied in field studies of autopsies and laboratory work arising from a widespread outbreak of a respiratory disease among young pigs. Rapid and successful progress has been made in investigating the life-history of a parasitic fly which attacks and destroys the larvæ of the clothes moth. The research has indicated other problems related to the use of parasites for the destruction of pests and also to the nature of the physiological relation between the host and the parasite.

The work of the Textile Department has continued to expand, and much of its testing work in 1940 was in connexion with fabrics and other materials manufactured for war supplies. Co-operative work with various firms associated with the quality control plan, in which eighteen manufacturers of fabrics and eighty manufacturers of garments are now co-operating, has been concerned particularly with work on the relation between seam construction and serviceability, effects of different finishing processes on the strength of dress fabrics, a comparative study of length of life of wool socks and wool plus rayon socks and the influence of time and other factors on the extensibility of drapery fabrics. Work on the response of silk to water vapour has been extended to cover a number of organic substances such as alcohols, ethers and ketones.

The investigation of the principles of scouring has continued, while in the Division of Engineering and Metallurgy, in addition to important testing work, studies have continued on the resistance of various alloys to abrasion, the malleability of white cast iron in relation to variation in chemical composition and the influence of the cross-sectional area of a test piece on the fatigue strength as measured by the Avery machine.

The Chemistry Division has largely been concerned with analytical work in connexion with specifications, while in the Division of Biochemistry, research in the leather laboratory has been concerned with further improvements in the methods of intermediate alum and chrome re-tannage of heavy leathers. Work has continued on methods for the preparation of organic acids by fermentation as well as the preparation of pure lactic acid for edible and medicinal purposes. Much of the effort of the Biochemistry Division has been given to determinations of vitamins in mill and other food products. The Department is collaborating in the development of rapid cheap and reliable methods for the determination of vitamin B_1, and is already in a position to carry out accurately and economically biological or chemical assays of vitamins A, C, D and B_1 constituents and riboflavin.

USES OF THE 200-IN. TELESCOPE

DR. MAX MASON, chairman of the Observatory Council of the California Institute of Technology, speaking at a meeting in June of the Pacific Division of the American Association for the Advancement of Science and the Astronomical Society of the Pacific, stated that the great 200-inch telescope to be erected on Mt. Palomar is now approaching completion, thirteen years after the late Dr. George Ellery Hale convinced the Rockefeller Boards of the feasibility of such an instrument, and obtained funds for its construction. It will be recalled that Dr. H. Spencer Jones gave some details about this instrument in his Thomas Young Oration before the Physical Society (NATURE, June 14, p. 753).

The disk, about 17 ft. in diameter, originally weighed 21 tons, and during five years' grinding at Pasadena, more than four tons of glass have been removed. The disk is carried by a system of thirty-six levers inserted in the holes of the ribbed back. Both the method of support and the structure of the mirror are new in this instrument. The supporting system must operate so perfectly that no bending of the reflecting surface beyond one or two millionths of an inch will occur as the telescope moves. As the surface of the mirror was brought by polishing close to a spherical form it became clear that the disk, when tipped from the grinding table to a vertical position for optical test, sagged slightly under gravity. This sag has now been eliminated by installing a system of twenty-four squeeze levers, operated by counter weights, distributed around the rim of the glass. The spherical surface required has nearly been reached, after which it will be changed to a paraboloid by deepening the centre concavity five thousandths of an inch.

Dr. Mason stated that it is doubtful whether the new instrument will be useful for photographing moon or planets, due to shakiness of the air, which destroys detail. Instead it will be used to study faint and distant galaxies, and to analyse in high detail light from the stars and planets.

Dr. John Strong, also of the California Institute of Technology, stated that one of the uses of the 200-in.

telescope will be to study planetary radiations. Planets not only reflect visible light which they receive from the sun; they absorb and then re-radiate considerable quantities of solar energy, largely in the form of the invisible infra-red rays. The special instruments and techniques necessary for the analysis of these radiations are being developed by members of the Institute staff. Much of the information necessary for comparison of conditions on the planets with those on the earth can be obtained only by a more careful and exact study of physical processes taking place on the earth's surface and in its atmosphere. Determinations, to an entirely new order of exactness, of the effect of water vapour, carbon dioxide, ozone and the major atmospheric gases on radiation, are on the programme of research. Incidentally, Dr. Strong pointed out, data obtained in these researches will probably be of very considerable value to meteorologists as well as to astronomers.

EQUATORIAL REGIONS OF THE PACIFIC

IN his address on June 18 as president of the Pacific Division of the American Association for the Advancement of Science, Dr. H. U. Sverdrup, director of the Scripps Institution of Oceanography, stated that the Pacific Ocean is two feet higher on the Australasian side than it is on the American.

As a result of this difference in elevation, there is a narrow, relatively swift current flowing eastward along the equator. If it were not for the friction of water against water, it would move at a rate of about seven knots. Its actual rate is one or two knots. This, however, is as rapid as the current in a great many inland rivers.

The pile-up of water against the Pacific's western shore results from the action of the trade winds. Steady winds blowing across the water from the north-east in the northern hemisphere's lower latitudes, and corresponding winds from the south-east in the southern hemisphere, keep two great currents moving steadily westward in the tropical Pacific. Separating them, in the equatorial belt of calms, is the narrow return current, flowing like a river.

This narrow west-to-east equatorial current, however, accounts for only a small part of the water returned across the Pacific. Much larger streams flow away from the equator, to make the return trip at higher latitudes. In the northern hemisphere, the principal returning mass is borne in the Kuroshio or Japan current, which sweeps along the Aleutian chain and turns southward along the North American coast. It is estimated that this current carries more than five thousand times as much water as the Mississippi.

As described by Dr. Sverdrup, the Pacific is a cold monster with a relatively thin, warm skin. Surface temperatures are quite high, reaching as much as 75° F. But this warm surface layer extends downward only a few hundred feet at most. The great bulk of Pacific ocean water, in the depths, is always cold, most of it only a few degrees above freezing-point.

EXTRACTION OF GOLD FROM SEA-WATER

WITH about five million pounds worth of gold dissolved in each cubic mile of sea-water, man has often sought a way of digging out this treasure. Using electrochemical methods, comparable to those used in electroplating, gold has actually been extracted from the ocean, but unfortunately the cost of the process is five times the value of the gold obtained.

Hopes that this may be reduced to the point where gold may be profitably extracted were raised by Dr. Colin G. Fink, of Columbia University, speaking before the Wilder D. Bancroft Colloid Symposium at Cornell University.

In electroplating, the metal in the plating solution is deposited on the cathode, the negative terminal. But when an effort is made to plate the gold out of sea water in this way the metal precipitates out rapidly, and fails to collect in the solid, crystalline form in which it is desired. By using a rapidly spinning cathode in place of the stationary one, it has been found possible to get a distinctly visible gold deposit. It is the cost of providing the spinning cathode that makes the method impracticable commercially.

In his search for the reason why gold fails to deposit on the stationary cathode, Dr. Fink made the discovery that, when gold passes out of or into solution, two distinct steps are involved. Invisible dissolved gold first goes into myriads of minute particles of colloidal gold, and then later into the crystalline form of the metal. The stationary cathode fails because the metal precipitates out in colloidal form and drops away before crystallizing.

Now a problem remains, namely, conversion of the colloidal gold into the metal crystals. Perhaps it can be accomplished with high-voltage electric currents, or with bombardment of electrons. Dr. Fink intends to try these. "In any event," he said, "it is felt that, on the basis of the discovery, we have advanced one step closer to the commercial recovery of gold from sea water."

Apart from this, however, the discovery is of great theoretical significance, and has practical importance as well. For example, it may hasten development of formulæ for the electroplating of metals such as titanium and vanadium. In this way, it may have far-reaching commercial results whether the gold extraction is accomplished or not.

THE WORONORA DAM, SYDNEY

AT present four large dams serve the metropolitan area of Sydney with its water supply. The Woronora dam, which is now nearly completed, is in the Upper Nepean catchment, and serves Sydney through a separate pipeline. This will greatly increase the margin of safety against any possible failure of supply to Sydney, which has a population of nearly a million and a half. The dam is a mass concrete structure with a crest length of 1,300 ft. According to the *Commonwealth Engineer* of May 1, it will be 217 ft. high above foundation level and will impound approximately 15,800 million gallons.

After completing the excavation in the river bed, a large number of deep holes were drilled in the floor of the cut-off trench and over the remainder of the foundations. Into these holes liquid cement was pumped to seal up any cracks or fissures in the underlying rock strata. The rock surface was then made spotlessly clean by means of compressed air and water jets, after which concreting was commenced.

The impounding of about 15,800 million gallons of water by the dam across the Woronora River will result in the submergence of one thousand acres of river valley. This area, originally heavily wooded, is being cleared to prevent pollution of the water. Trees are felled, the larger ones broken up by blasting, and the undergrowth is cut down. After a short interval for drying, a running fire is allowed to pass over the area to burn off the small branches and leaves. The remaining timbers are then stacked and burnt.

An inspection gallery runs longitudinally through the dam at a height of 60 ft. above the river bed. An additional gallery is being constructed along the rock foundation to the southern abutment where excavation has revealed very broken strata. The 36-in. outlet pipes at the base of the dam are controlled at the upstream end by timber stopboards, emergency roller gates and penstocks. At the downstream end the outlets are connected to the 48-in. diameter steel delivery main which forms the Woronora pipeline, and are each controlled by a gate valve and a needle valve. A spillway channel, 30 ft. wide at the bottom and with a maximum depth of 150 ft., is being excavated through a spur to provide for the maximum flood discharge of 36,000 cusecs. This channel will be concrete built up to about flood level.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEAD OF THE CHEMISTRY AND APPLIED CHEMISTRY DEPARTMENT—The Principal, Stockport College for Further Education, Stockport (August 15).

LECTURER IN MINING—The Registrar, University College, Nottingham (August 16).

HEADMASTER to re-open British School at Punta Arenas, Chile—The British Council, 3 Hanover Street, London, W.1 (endorsed 'Chile') (August 20).

ENGLISH MASTER for the Grange School, Santiago, Chile—The British Council, 3 Hanover Street, London, W.1 (endorsed 'Santiago') (August 20).

LECTURER IN MECHANICAL ENGINEERING at the School of Mines and Technology, Treforest—The Director of Education, County Hall, Cardiff (August 20).

ASSISTANT LECTURER IN MATHEMATICS—The Registrar, The University, Manchester 13 (August 22).

LECTURER IN ELECTRICAL ENGINEERING, and LECTURERS IN PHYSICS AND MATHEMATICS—The Registrar, Loughborough College, Loughborough (August 23).

ASSISTANT TO THE CHIEF ENGINEER—The General Manager, Manchester Ship Canal Co., Ship Canal House, Manchester 2 (endorsed 'Personal') (August 25).

DIRECTOR OF EDUCATION—The Town Clerk to the Local Education Committee, Town Hall, St. Helens, Lancs. (August 25).

CHIEF EDUCATION OFFICER—The Education Officer, The Town Hall, Chesterfield (August 26).

TEACHER (MAN OR WOMAN) WITH GOOD QUALIFICATIONS IN BIOLOGY, PHYSICS AND MATHEMATICS—The Headmaster, Dartington Hall, Totnes, Devon.

DIETITIAN—The Food Supervisor, Royal Masonic Hospital, Ravenscourt Park, London, W.6.

LECTURER IN MATHEMATICS—The Principal, Rugby College of Technology and Arts, 61 Clifton Road, Rugby.

MASTER FOR SCIENCE AND ENGINEERING SUBJECTS—The Principal, Sheerness Technical Institute and Junior Technical School, Sheerness.

REPORTS AND OTHER PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

The Journal of the Institute of Metals. Vol. 66, 1940. Edited by N. B. Vaughan. Pp. xxxii+449+70 plates. (London: Institute of Metals.) [217

Metallurgical Abstracts (General and Non-Ferrous). Vol. 7, 1940. Edited by N. B. Vaughan. Pp. xii+652. (London: Institute of Metals.) [217

SOCIAL EDUCATION IN THE SERVICES

A GOOD deal has been said and written in recent weeks about education in the Forces, or the lack of it. It is generally agreed that something needs to be done, although there may be considerable difference of opinion as regards steps which might be taken.

Among the often conflicting evidence, particular weight must be attached to that of the men most concerned, namely those actually in the Forces. Among officers the complaint has been heard that army education is virtually non-existent, and men in the ranks have been heard to tell the same story. There are graduates in the ranks who will vouch that repeated inquiries after lectures have had no effect, and cases are even known of names having actually been collected for lectures which never materialized. Much of the complaint must, of course, be discounted as unavoidable. In addition to the static units, there are mobile units which are liable to very frequent removal about the country-side, and even the so-called static units must of necessity be moved on occasion. Removals such as these will naturally render more difficult the organization of army education, but they are scarcely an excuse for the conditions obtaining in some units.

There have been suggestions that the whole educational work of the armed forces should be organized on a compulsory basis, and recently there have been moves in this direction as regards one particular range of subjects. But in general the military authorities insist that the attendance of the men must be voluntary. Here a distinction must be made between the different types of instruction available. There are the purely training lectures, which, of course, must necessarily be compulsory. Then there are what may for convenience be termed vocational lectures, in subjects not directly connected with immediate military necessity, but likely to be of pecuniary advantage to the men on their return to civil life. Here, however, we are concerned much more with 'interest' lectures of no immediate military concern and of no likely financial advantage. Many people will be found to say that to take men away from their civil life and conscript them for military service, and then to hesitate to take an occasional hour of their free time for a lecture, is to swallow a whale and strain at a gnat. But there will be general agreement with the official view that men should not be forced to attend non-military lectures.

There is, however, among the men a considerable demand for voluntary lectures of this nature. Organizations, whose function it is to arrange lectures in different parts of the country for the civil population, report that men in uniform attend their lectures in considerable numbers,

although there is clearly not a trace of compulsion to do so. In fact, in some areas it has been known that the uniformed members of the audience have outnumbered the civilians. A major distinction exists in this respect between the three services. In general, shore naval establishments are so busy with purely instructional work that the men have neither time nor inclination for further lectures, and to a lesser degree the same is true of the Royal Air Force. But this is by no means true of the army. Vast numbers of men do not know what to do with their spare time. Granted that a certain amount of leisure is wisely spent on amusement, there still remains too much time on hand during which men would gladly be occupied. This state of affairs must inevitably lead to boredom, and one would expect it to be of major concern to the military authorities.

The main difficulty seems to be that although there is this desire among the men for lectures, the official machinery for translating the desire into the lecture does not in many cases function. Its efficiency, of course, varies much from unit to unit. Where the education officer is a man with his heart in his educational work, the possibility of organizing interest lectures will not merely be brought cursorily to the men's notice by occasional announcement or poster, but will be impressed continuously and actively upon them, and it will be emphasized that any request for a lecture will be listened to sympathetically and, where at all possible, granted. The crux of the matter is this need for the initiative to come from the ranks.

There is no doubt that a really determined seeker after enlightenment, who is prepared to persuade a few comrades to support him, can make it rather difficult for an education officer of a unit to refrain from arranging lectures. But is it fair to expect men to take such steps? And can we not readily understand if men feel that it may not react to their advantage to act in this way? Surely it should not be necessary for the provision of cultural lectures to depend upon the presence in a unit of men of rather exceptional initiative. It might be possible, for example, while retaining to the full the voluntary nature of the men's attendance, for education officers themselves to arrange attractive lectures for the men as an experiment. If as a result of experience it were found that men would not attend, other methods would have to be adopted. But all the evidence suggests that many would be glad of the opportunity of spending some of their spare time in this way.

There must be many bodies, national as well as local, which are able and willing to undertake interest lectures to the forces. On the biological side, such topics may be suggested as the human applications of biology, some of which are capable of presentation in a way directly concerned with the ideological struggle in which the men are engaged. The Nazi myth of an Aryan race of supermen, for example, could be used as a basis for anthropological lectures. Then there are all the problems of the history and development of the family, the entrancing subjects of evolution and heredity, in which there is widespread interest. On the physical and chemical side, the possibilities of dealing with applications are equally numerous, though care would of course have to be exercised to avoid making such lectures appear to be supplementary to instructional lectures at which attendance is compulsory; nevertheless, we believe that many soldiers would be quick to perceive the value of knowledge acquired by this means in their military duties. Geology should also provide good topics. A moment's consideration will show that outside the sciences also there are numerous opportunities of engaging interest. There is a far too common tendency to underestimate the intellectual level of the men in the Forces. It seems often to be assumed that so soon as a man dons khaki, he puts away all his normal mental interests and becomes a mere number. The army to-day is a fair cross-section of the younger civil population, and will have the same interests and intellectual level.

If, as is to be hoped, lectures become more easily available to the men, there will be a demand for lecturers which cannot be met from normal resources, and that will present to scientific men and others an opportunity to perform a most valuable piece of service to their fellows. There must be many who, under competent organizations, could give useful lectures; this applies with particular force to teachers, who have the vitally necessary training in presenting subjects in a simple and intelligible form. Moreover, there must be at present, in the armed forces themselves, large numbers of men who are excellently qualified to carry on this work.

It seems to be overlooked by those in authority that the present army is a body of citizens who are being trained for the purpose of defeating a specific enemy. It is not, and indeed cannot be, an army of professional soldiers. This is not meant in any disparaging sense, but solely to emphasize that the great majority of the men now serving are temporary soldiers, each of whom is looking forward to the time when, having defeated Nazism by force of arms, he can return to civilian life. He is entitled to expect that he shall be afforded opportunities of fitting himself to take his part as an earnest citizen in building up a new and better world order, and are only waiting for an opportunity to do so.

RECRUITMENT AND FOREST POLICY

AFTER seventy years of forest administration in India and Burma, and nearly forty years in some of the British Colonies, it is disturbing to realize how little the importance of the forest wealth of some of the countries in question is understood in Great Britain or by the responsible administration. The general attitude of administrators is apparently that forest property, especially great areas of tropical and semi-tropical forests, can be left to look after themselves when any period of stress, financial or otherwise, eventuates. These ideas are strongly entrenched in Government circles, particularly in London.

The present position with regard to the training of foresters is causing considerable concern. Whereas men taking certain technical degrees at universities are to complete their studies before being called up for military (or other) service, those taking a pass degree in forestry are not to be retained. This action has been taken apparently after referring solely to the Forestry Commission, which, being at present chiefly a spending department, has of necessity ceased recruiting. In reply to a recent inquiry the Ministry of Labour and National Service stated that the experience of the Central Register is that the demand for pass degree forestry men is almost non-existent. The Central Register has apparently been notified of only two vacancies for such men over the last six months, and both these were offered by the Sudan Government. The position with regard to the demand for agricultural students is of course very different.

The information thus conveyed is not even accurate. At about the time of, or slightly before, the offer of the Sudan appointments, the Punjab Government was offering two appointments for men possessing forestry degrees and was unable to obtain them. Further, the Colonial Office, though much slowed down, had not ceased recruiting. The recollection there was only too vivid, as it should be in India also, of the crucial difficulties in connexion with filling the ranks of forestry services after the War of 1914–18; and of the troubles which inevitably resulted from recruiting excessively large annual batches often inefficiently, because hurriedly, trained.

It may be asked, it being incontrovertible that the millions of the peasant agricultural populations are in one way or another dependent upon these great forest regions in the British Empire, whether ministers and their deputies responsible for the administration of these several countries really understand the position. The forest departments have been cut down, by allowing junior officers to join the Fighting Services and reducing annual recruitment. At the same time, it is well known that enhanced fellings are taking place to provide for military requirements. No forest, whatsoever its type, can stand this kind of treatment without serious deterioration. Moreover, such fellings are often, in the absence of the supervision of trained and responsible forest officers, put into the hands of uncontrolled timber contractors who have no other interest than to complete their contracts at whatever the cost in destruction to the forests.

Under the British system of Colonial administration, it is constantly reiterated that we are governing the countries in the interests of the people, and that when they are ready the government will be entrusted to them. But how are the forests being treated? What will be their condition when we make over this charge? The old Colonial policy was to give a long lease of a block or blocks of forests to a big timber company which paid a royalty, usually so much per tree felled; and it was considered that such arrangements were in the interest of the development of the Colony. Many fine forests have disappeared under this treatment—but their marketable value, that is, the money resulting, mostly left the country. Take, for example, Nigeria at the present time, and the valuable mahogany timber. Under present conditions, Government, that is, the people, obtain about £4 in royalty for a tree selling at present prices for more than £100—and much of this difference goes out of the country. Further, the forests so worked are not under the supervision of trained forest officers.

War does not stop the working of these tropical forests; it tends to enhance it. The staff requires additions, not cuts—as should be evident, if the case were rightly understood, to a wide-visioned administrator. It is not a question of planning ahead. Rather it is that of fulfilling a sacred obligation to the people we govern by handing down to their successors a better heritage; and that the present profits should be spent on the people themselves.

The Secretary of State for the Colonies recently said in the House of Lords: "Not only colonial trade but also colonial development in the widest sense will inevitably have to be regulated and controlled by Government much more than was necessary before the War." The position of forestry in the British Colonies may be commended to the personal attention of the Secretary of State.

DYNAMIC DEMOCRACY

Faith for Living

By Lewis Mumford. Pp. viii+248. (London: Martin Secker and Warburg, Ltd., 1941.) 7s. 6d. net.

WHEN President Roosevelt on September 3, 1940, in a broadcast to the United States, announced the outbreak of war, although two days later he proclaimed the neutrality of the United States, unlike President Wilson in 1914 he said that he could not enjoin neutrality of thought. The contrast is significant. Anglo-American co-operation has two aspects. There is first the community of ideals, of tradition and of thought. This is itself the firm basis for the second aspect—the practical measures of co-operation, the evolution of technical methods and of common policy in the face of a challenge to these common ideals and traditions, hammered out in part, at least, on the anvil of war.

The pace at which co-operation has advanced in this practical sphere from the establishment of the joint Canadian-American Defence Board in August 1940, the lease to the United States of British bases in the Caribbean and the Atlantic, the assumption by the United States in April 1941 of the responsibility for the defence of Greenland, the passage of the Lease-and-Lend Act, the Atlantic patrol, to the proclamation of an Unlimited National Emergency has tended to overshadow the first and fundamental aspect. That community of ideals and tradition has, however, been admirably illustrated and emphasized in successive speeches of President Roosevelt—for example, in those four reprinted under the title "Mr. Roosevelt Speaks" in the first of a series of pamphlets, "America Faces the War", issued by the Oxford University Press. They are equally displayed in the speeches of the late Lord Lothian, of Lord Halifax, of Mr. J. G. Winant, and notably in Mr. Eden's speech of May 29.

Mr. Eden's speech no less than Mr. Winant's notable address to the English-Speaking Union on May 14 reflected the depth of those common ideals and the firmness of the common resolve to defend them and to ensure that the four freedoms of which Mr. Roosevelt has spoken should be the lot of all men and not the privilege of the few. Mr. Eden indeed, after welcoming Mr. Roosevelt's message on the freedom of the seas as the condition of the continued existence of free nations everywhere, dealt chiefly with the third of those freedoms, namely, social security or freedom from economic want, and what it would involve in the days immediately after the War.

This fresh assurance to the world that the British Commonwealth means to co-operate with the United States in the creative task that President Roosevelt has described as his main purpose gives further point to the study of American history, institutions and traditions, particularly by the rising generation in Great Britain. Without at least an understanding of the American tradition, even scientific collaboration between the two countries—the pooling of information, the development of joint activities and the exchange of students and research workers, described by Prof. A. V. Hill in a recent article in *The Times*—cannot attain its full effect. A determined effort in this field is an essential for the fruition of the conception of American partnership with the British Empire in world leadership, of which the twentieth century has seen the birth.

Mr. Mumford's book now under notice is a valuable contribution to such a mutual understanding. Written in the United States and addressed exclusively to his own countrymen, as the author points out in a preface to the English edition, the first response has come from the British people. In the searching test of the summer and autumn of 1940, they set an example of what free men throughout the world must demand of themselves if any life worth living is to survive. Mr. Mumford's book throws a vivid light on the ideals and faith on which Anglo-American co-operation is based. It is a summons to realistic thinking and a challenge to action, rather than a statement of a creed or a faith upon which he insists all courageous and noble living must be based.

The moral cement that held democratic Western society together had practically disappeared by 1930, largely because the twentieth century inherited a morality for which it had never worked, which it had never examined or assimilated and which, accordingly, it was incapable of reproducing in fresh forms. This is, in Mr. Mumford's view, the fundamental cause of the drift, inertia and despair which have given Nazism its opportunity. That faith can only be countered effectively by one as strong and passionate, equally capable of fostering devotion and loyalty, and commanding sacrifice.

Mr. Mumford fully recognizes the role of reason and the significant contribution of science to human personality itself as the most effective method man has discovered for securing agreement in areas

where rational demonstration is possible. But he sees, too, how failure to take account of the material and spiritual needs of man has now endangered the world-wide co-operation upon which the growth of science, technical development and industrial wealth depends, and he writes scathingly of those who are blind to the values of truth, justice, freedom and love, which are the basis of society, and who can see only the destructiveness of war.

Mr. Mumford's searching scrutiny of the failure of the Churches is not unfair or unsympathetic to the values they represent, but he insists on the necessity for a central core of purpose, for a re-birth of the positive values of life, for a new and passionate loyalty to the spirit which gave the Churches their power, and the capacity for sacrifice which gives power to life. Searching for a new faith for living, Mr. Mumford does not indeed give us much more than this. His vision is wide and he sees life steadfastly and as a whole. He urges a return to a true regional, family and personal life and an economy of sacrifice instead of comfort. He indicates the opportunities which are ours, rather than points the way to a new faith. But his passionate sincerity makes his book as vital as his keen analysis and constructive thought. Like the Hebrew prophets, he mingles stern warning with a call to high endeavour, and the sanity and balance of the book should give it particular appeal to the many scientific workers who are already bending their efforts to the forging of firm links between the Anglo-Saxon democracies in their resistance to the gravest threat which the world has yet known to man's spiritual, moral and cultural heritage. Upon the response to that challenge may well depend the success of Anglo-American co-operation whatever form it takes.

R. BRIGHTMAN.

CHEMISTRY IN RELATION TO MEDICINE

Chemistry and Medicine
Papers presented at the Fiftieth Anniversary of the Founding of the Medical School of the University of Minnesota.
Edited by Prof. Maurice B. Visscher. Pp. vii+296. (Minneapolis: University of Minnesota Press, 1940.) 4.50 dollars.

IN 1939 the University of Minnesota Medical School celebrated its fiftieth anniversary. The committee of the Medical Faculty which had been appointed to draw up a scientific programme appropriate to the occasion decided to invite a number of distinguished men of science to deliver lectures upon different aspects of the single theme of "Some Trends in Medical Progress with Particular Reference to Chemistry in Medicine". The publication of these lectures in a single volume under the title of "Chemistry and Medicine" should be warmly welcomed by all those in Great Britain, research workers and teachers alike, who are interested in the medical sciences, and certainly will be by those who, like the writer of the present notice, believe that our own university medical schools would fulfil their proper functions of training medical students and of carrying out original research more efficiently if something of the American attitude towards the basic sciences—particularly towards chemistry—were adopted.

In his foreword to this volume the Dean of the Medical Faculty states that "this subject was chosen not because it is more important than other fields of medicine but because it represents one of the most recently developed and more rapidly expanding aspects of medical science". The view expressed in the latter half of this statement appears to sum up very well the general attitude towards the basic sciences which is found in the leading medical schools in the United States. Doubtless there would be few in the medical schools of Britain who would challenge its essential correctness, but while the Americans have the courage of their convictions and act in accordance with them, we have not and do not. Thus we pay little more than lip-service to the importance of chemistry and physics in our medical curricula; courses are provided in these subjects that are scarcely more suitable as a preparation for the study of biochemistry and physiology than are the ones provided in our secondary schools. We are, in fact, in grave danger of forgetting that the latter subjects, which may be said with considerable justification to form the basis of modern scientific medicine, have advanced so much during recent years that they can no longer be properly understood with only a schoolboy's knowledge of chemistry and physics. Considerable reforms in our medical curricula are clearly desirable and inevitably must be instituted sooner or later. It is perhaps not too much to hope that this University of Minnesota publication may indirectly expedite the institution of these much-needed reforms by bringing home to medical faculties of British universities the realization of the extent to which they have lagged behind the Americans in their attitude towards the more scientific aspects of medicine.

The fourteen articles which the volume contains are grouped under four headings: "Progress in the Application of Physical Chemistry to Medicine", "Some Recent Investigations in Metabolism", "Some Aspects of Immunity and Chemotherapy", and "Some Approaches to the Nervous Control of the Organism". All the articles are good and are packed with information, although in some the subject-matter is presented in a much more interesting manner than in others. The ones which the present writer particularly enjoyed reading were those by Prof. J. P. Peters on "Some Reactions by which Solutes may be Differentially Concentrated by the Kidney", by Dr. M. Heidelberger on "Recent Chemical Trends in the Study of Immunity", and by Prof. W. B. Cannon on "The Argument for Chemical Mediation of Nerve Impulses".

Prof. L. E. Smith's article on "Organic Chemistry in the Pursuit of Vitamin Research" contains an excellent and comprehensive account of recent chemical work on vitamins E and K. The article is so full of 'meat', however, that one cannot help wondering whether Prof. Smith's audience did not suffer slightly from mental indigestion. Prof. R. G. Green's article on "The Biology of Animal Viruses" will be valuable as a corrective to those who have too enthusiastically embraced the view that all viruses are chemical compounds rather than living organisms in the generally accepted sense of that somewhat vague term. It is difficult, however, to pass without comment Prof. Green's statement that "Work on crystallisation has fostered the general belief that viruses are relatively simple chemical compounds". Surely proteins the molecular weights of which amount to several millions can scarcely be properly described as "relatively simple chemical compounds".

Although not all the articles in this volume can strictly be said to be chemical in outlook, they form as a whole a most striking testimony to the value and importance of the recent contributions to medical knowledge made by chemistry, and in particular by American biochemistry.

G. F. MARRIAN.

THE GROWTH OF SCIENCE

A Short History of Science to the Nineteenth Century

By Charles Singer. Pp. xiv+400. (Oxford: Clarendon Press; London: Oxford University Press, 1941.) 8*s*. 6*d*. net.

CONTEMPORARY events have given the study of the history of science a new and profound importance. It is evident that science is having cataclysmic effects on human society. The investigation of the nature and origin and possibilities of science, in addition to its advancement, has become an urgent necessity as a preliminary to any considered action for human betterment. The old antiquarian notions of the history of science have been submerged in a new living attitude to the subject, which has been forced forward by present needs.

For these reasons, the appearance of Dr. Singer's new book is particularly welcome. He has aimed at the presentation of the salient facts in the development of science from Græco-Roman times until the middle of the last century. He finds the origin of science in the struggles of early man with his environment. He instances the cave drawings of bison with arrows sticking in the heart, which record the beginnings of anatomical and physiological knowledge. The foundation of astronomy was associated with the development of agricultural societies, which require a calendar for the determination of the seasons for sowing and reaping. The very word geometry means 'earth-measurement', and the invention of numerical notation was associated with the development of commerce.

These, and many other examples, show the age of scientific activities, and how they are embedded in the evolution of man and his societies.

Dr. Singer is not satisfied with the definition of science as a body of knowledge. He remarks that history has shown repeatedly that a body of knowledge which is not in process of growth rapidly withers, and ceases to be science at all. Science must therefore be an active process. He points out that the word 'scientific' means by derivation 'knowledge-making', and no static definition of science as a body of knowledge is satisfactory.

Dr. Singer starts his history, however, with the Greeks, not because they were the first men of science, but because they were the first who were conscious of science as a distinct process. He treats the history of Græco-Roman science in four chapters. The first deals with the emergence of the idea of mental coherence in Ionia, and its development by the Pythagoreans and the

Athenians. The second contains an account of the work of Plato and Aristotle and their immediate successors, which he describes as a great adventure in search of unitary systems of thought. Then the work of the Alexandrians is analysed. The divorce of science and philosophy is noted, together with a failure of intellectual nerve.

In the Roman period, science became the handmaid of practice, and was accompanied by a general failure of intellectual inspiration. This was followed by an almost complete failure of knowledge during a whole millennium. Then there was a revival of humanism and an attempted return to the culture of antiquity. The downfall of Aristotelianism was accomplished at the start of the seventeenth century, and was accompanied by new attempts to give a synthetic description of the universe and Nature. The Newtonian mechanistic scheme and determinism were enthroned. and have endured until recently. Dr. Singer finds no change of method since the seventeenth century, but only an immense extension of scientific knowledge.

His comments on the relations between the Christian outlook and the development of science are very interesting, and are supported by excellent quotations from St. Augustine and other fathers of the Church. He discusses with unusual illumination the contributions of Syrian and Jewish scholars, and he shows how much of what passes as Arabic science was really due to them.

The stages of the change of ideas during the passage from pagan to Christian thought are most conveniently summarized in half a page. The fundamental premises of alchemy are epitomized in the same way, and there are similar summaries of Goethe's contributions to biology; Schwann's theory of the cell, Claude Bernard's conception of the internal environment, and the origins of the theory of evolution.

Dr. Singer's learning is always exact, as befits the senior British historian of science. His book is full of fascinating information, and will at once become a standard work on the history of science both for the man of science himself and the general reader.

J. G. CROWTHER.

STUDIES IN BACTERIOLOGY

General Bacteriology

By Prof. D. B. Swingle. Pp. xii+313. (London: Chapman and Hall, Ltd., 1941.) 16*s*. net.

THE method of presentation of a subject taught at every university by a writer of another nationality differs, of course, from that customary in Great Britain. It is only fair to say that the distinction may be more apparent than real, and that it is usually a question of manner, not of matter.

Prof. Swingle has a standing in his subject which transcends mere geographical boundaries. A textbook by him therefore on his own subject rightly arouses interest. He has drawn freely on his own experience in teaching and research in determining the lines on which he has drawn it up.

Micro-organisms are closely related to the whole problem of disease; they play also an important part in the manufacture of certain industrial commodities, such as dairy products and alcoholic beverages, and incidentally the curing of tobacco. The importance of these relations explains why bacteriology tends to be given a secondary place in that it is usually considered from the angle of one or other of its effects or uses. Prof. Swingle rightly prefers to present the subject as a science in itself; thus therapy alone is permitted a homogeneous and complete description. The details, helpful or otherwise, of the activities of micro-organisms in their practical aspect are by no means neglected but are given proportion corresponding to their importance.

"General Bacteriology" thus offers a systematic approach to the subject as a whole. The fundamental principles are fully covered and proper space allotted to the important aspects of classification, morphology, reproduction, growth, nutrition, relations to environment and the products of bacteria. After covering this groundwork, Prof. Swingle goes on to micro-organisms of soil, of water, air, sewage and foods, proceeding in natural sequence to discuss contamination of food, industrial micro-biology, and the relations of bacteria to disease processes, infection and immunity.

Prof. Swingle writes in a simple, straightforward style, easy and readable. The illustrations are adequate in number and in applicability. The book can be commended as a thoughtful and balanced presentation of the subject of bacteriology as a whole.

J. GEOGHEGAN.

Entomophagous Insects

By Curtis P. Clausen. (McGraw-Hill Publications in the Zoological Sciences.) Pp. x+688. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 49s.

THE last thirty years, or thereabouts, have been productive of great advance in our knowledge of entomophagous insects. This accumulated information is largely the outcome of the increasing use made of the biological method of pest control, which has stimulated investigation of both parasites and predators. Mr. Clausen is a distinguished entomologist on the staff of the U.S. Department of Agriculture. His own studies have been mainly directed to the parasitic Hymenoptera and he is well qualified to write a book of this kind.

The subject-matter is arranged under the orders and families concerned, beginning with the Hymenoptera and ending with groups of lesser importance. The author adheres closely to the limits imposed by the title of the book, and consequently little or nothing is said regarding other carnivorous insects attacking various invertebrates, birds or bats or other mammals. As it is, the book is one of very considerable dimensions for so specialized a subject, but it is a veritable mine of carefully collated information. The extraordinary adaptations to various modes of life, and the great diversity of larval forms betrayed by so many of the insects under consideration, provide unique material for a most interesting biological story.

The book is one written essentially from an entomologist's point of view, and those who consult it will find therein a great deal of information that has not previously appeared in any manual. A feature of special value is the 46-page bibliography at the end of the last chapter. The general biologist who peruses its pages will feel some disappointment in the restricted treatment of the remarkable phenomena associated with insect parasitism and their theoretical implications. Notwithstanding this limitation, the author is to be commended on having written a valuable and, in some ways, unique volume. It is to be regretted, however, that it has been found necessary to price this work at so high a figure, thus placing it out of reach of many of the younger potential purchasers. A.D.I.

The West Highlands and the Hebrides

A Geologist's Guide for Amateurs. By Alfred Harker. Pp. xxiii+128. (Cambridge: At the University Press, 1941.) 8s. 6d. net.

THE West Highlands and Islands had a warm admirer in Alfred Harker, and it is therefore not surprising that he had long contemplated the writing of a book by which he might share his knowledge of the region. Unfortunately, Harker died before his project was fully completed, but with the help of others the book is now published in homage to his memory. A pathetic interest is attached to the biographical sketch of Harker contributed by Sir Albert Seward; it was written shortly before his own death.

Harker's plan was to describe the region in terms which would appeal to travellers and others interested in geology and scenery. This has been accomplished in chapters arranged as a series of excursions, and his description of the richly varied character of its rock formations will prove useful to geologists and geographers alike. The volume is profusely illustrated by simple but effective outline sketches drawn by the author, and these have been augmented by the inclusion of geological and topographical maps. An excellent glossary meets the needs of the layman unfamiliar with the names of rocks and minerals.

There is little room for criticism; but the editor's omission of Kimmeridge rocks in the table of strata may be noted and, like the reference to the Permian, a footnote might have been inserted to explain that the greater part of the Durness Limestone is of Ordovician age.

The Annual Register

A Review of Public Events at Home and Abroad for the Year 1940. Edited by Dr. M. Epstein. Pp. xiv+478. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1941.) 35s. net.

SINCE 1758 the Annual Register has not failed to make its yearly appearance. The current volume maintains all the established traditions of the series. More than half the volume is occupied with the history of the year, first and in most detail British and Imperial, and then foreign history. For 1940 these chapters are virtually a history of the War and of Nazi intrigue. The story is told objectively. The remainder of the volume has the usual summary reviews of literature, art, finance and law, and obituaries of distinguished men and women. The public documents, printed in full, include notes regarding United States destroyers and naval and air facilities for the United States in British trans-atlantic territories; Memorandum of Agreement with General de Gaulle regarding French Forces; the Three-Power Pact of Germany, Italy and Japan; and the Norwegian Government's White Paper of April 1940 on German Aggression in Norway.

British Museum (Natural History). Instructions for Collectors No. 4A: Insects

Compiled by Dr. John Smart, with the assistance of other Members of the Staff of the Department of Entomology. Pp. vi+164. (London: British Museum [Natural History], 1940.) 1s. 6d.

THIS little manual is a great improvement on its predecessor and, for its very modest cost, provides practically all the information likely to be wanted for collecting and preserving insects. A useful addition is the well-illustrated section dealing with how to recognize the main groups of insects, when to collect and how to collect. The book should do much to aid potential and other collectors in obtaining material of scientific value and preserving it in a manner enabling the best use to be made of it. It can be highly recommended also to university and college students and to school natural history societies.

SCIENCE AND FAITH

SIR WILLIAM BRAGG's Riddell Memorial Lecture on "Science and Faith", delivered before the University of Durham at King's College, Newcastle-upon-Tyne, on March 7, which has now been published*, will interest all who wish for harmony between the different spheres of human thought.

The 'natural knowledge' which has grown so amazingly in the last three centuries is not so distinct in character from other knowledge that it is to be considered entirely by itself.

"The whole knowledge at our disposal is far greater than our modern science, as the whole is greater than the part. It includes the observations of countless generations of men, their experiences of life and the record of their thoughts thereon and the comments of their interpreters and lawgivers, the histories of the actions of nations and individuals especially in relation to the faiths on which they have acted, all in fact that men have learnt since they first began to learn."

Modern science is only a part of this mass of knowledge. If it is a new chapter in our book of knowledge, does it throw light on the chapters that have gone before? Is it going to help men towards a solution of the great problem of the choice of an attitude to life? Men have adhered to certain faiths: does science affect their present choice of a faith? Such are the questions raised by Sir William Bragg in his lecture.

"I would describe Science", writes Sir William, "as a collection of observations of Nature. There is an old word 'observables' which aptly describes the facts that the scientist is on the look-out for. Science observes the observables, tries to see what is noteworthy and records it. Gradually a mass of knowledge is accumulated which is sufficiently stable and reliable, so that it is worthy of study and can be used safely."

The man of science as he works must draw temporary conclusions from what he sees because in so doing he finds guidance in the next effort of discovery. If he made no attempt to plan his work he would lose himself in a mass of uncoordinated facts; hence he must try to find correlations, rules and laws. To grasp what he has already got would be impossible unless he did this.

"He therefore makes hypotheses. But it is to be observed that all such hypotheses are tentative, and are to be amended constantly as knowledge grows. There is no finality in these attempts to draw conclusions. Some are more enduring than others, but it can never be said of any law formed and used by the scientist that it is good for all time."

Sir William Bragg supplies three notable instances of universally accepted and to all appearance permanently secure hypotheses which in due course had to be revised in view of new knowledge. Such were the atomic theory of matter and the Newtonian theory of gravitation. Yet in neither case, Sir William points out, was the work of those who formed the superseded theory wasted or wholly invalidated. Chemists can still work with the atomic theory, knowing that the chances of any atom breaking down while in their hands are so small as to be negligible. And though Einstein has shown that there is a point beyond which Newton's theory begins to lack perfection, the astronomer's work is not affected.

The third instance of a scientific theory which had to be modified is a fine example of this need to abstain from dogmatism, which science teaches continuously. In his "History of the Inductive Sciences" Whewell spoke of the undulatory theory of light as the perfect example of a true and complete theory since it not only explained all that was known but also continually predicted new phenomena which were then found to exist.

"Yet there came a sudden end to this certainty when the properties of X-rays were made plain, and it became certain that they and light itself had corpuscular as well as undulatory properties. When, however, the work of the long years of development of the wave theory was reconsidered, it was found to be still well done and without flaw: the light really was a wave motion. Yet the new discoveries cannot be readily explained on any but a corpuscular hypothesis.

"Here then is a case where not only was the accepted and trusted theory in need of modification, but there is the added complexity that two hypotheses which are both supported by quantities of excellent proof seem to be mutually exclusive. There is as yet no simple explanation, in the sense that no clue has been found which would lead simply from one hypothesis to the other. A mathematical formula can be found which covers the two cases, and that is all."

There is thus a position "which seems nonsensical and is nevertheless true". This surely is a test case of science's dislike of dogmatism.

* Science and Faith. By Sir William Bragg. (University of Durham: Riddell Memorial Lectures, Thirteenth Series, delivered before the University of Durham at King's College, Newcastle-upon-Tyne, on March 7, 1941.) Pp. 24. (London: Oxford University Press, 1941.) 1s. 6d. net.

Passing on to the other side of his subject, Sir William Bragg accepts the definition of faith found in Hebrews xi, 1, that it is "the substance of things hoped for, the evidence of things not seen", which he calls "an unforgettable sentence obviously full of earnestness and meaning". The Greek would appear to convey the meaning that faith consists in regarding as already actual, things which are only as yet hoped for, and in an assurance that things not yet seen are nevertheless real. The writer of Hebrews supplies a number of instances of persons who "died in faith", that is, lived until death without surrendering this attitude of mind and will. Thus Sir William's interpretation of the sentence is sound, namely, that the writer's faith, "the faith which he held himself and preached to others, was a hypothesis so firmly held and trusted that he would and did stake his life upon it".

Hypothesis is therefore integral alike to science and to faith, and so forms a link between the two, and this is being more generally recognized on both sides.

"It seems to me that in recent years the way of the scientist and the way of the seeker for a good way of life have come to have more features in common than in the past, more than is generally recognized. If the scientist was ever unduly dogmatic he has ceased to be so: this one-time self-assertion at a time within living memory was in no small degree a weapon of offence and defence which he felt himself compelled to assume. In part it was a mistake of his own making. I should think that the theologian's dogma is now becoming more and more like the scientist's hypothesis, so probable of course that he accepts it and acts upon it always. If the theologian says that I am not justified in my statement, I shall still suspect that the disagreement is subject to a misunderstanding."

His point that hypothesis is of the essence of science and faith alike is of such importance that perhaps it deserves to be examined more closely than the limits on his space enabled Sir William Bragg to do. Are the two hypotheses, that of science and that of faith, the same in kind, or is a radical distinction to be drawn between them? The scientific hypothesis can be proved or disproved here and now by referring the matter to a controlled experiment; the appeal is to sense-experience and to 'facts'. But that the religious hypothesis cannot always be so proved is indicated by what the writer of Hebrews says of his exemplars of religious faith, "These all died in faith, *not having received the promises*". These people, some of whom he says died in torments, never received confirmation of their faith—at least not in this world. Even the last recorded words of the Founder of Christianity were "My God, my God, why hast thou forsaken me?"

It is, of course, true that the Christian 'way of life' can be tested in practice as to whether or no it 'works'. This is clearly what Sir William Bragg has in mind when he writes:

"Science is experimental, moving forward step by step, making trial and learning through success and failure. Is not this also the way of religion, and especially of the Christian religion? The writings of those who preach that religion have from the very beginning insisted that it is to be proved by experience. If a man is drawn towards honour and courage and endurance, justice, mercy, and charity, let him follow the way of Christ and find out for himself that it leads where he would go. No findings of science hinder him in that way, nor do they give any direct proof that it is the right one to follow."

Of course a pragmatic test of this sort must not be pressed to carry a weight of proof of which it is incapable. It can never establish the Christian religion as a body of principles with metaphysical validity. But is such a thing necessary? Science can dispense with metaphysics, so why not religion? But *can* science dispense with metaphysics altogether? Are there not involved certain "absolute presuppositions", as Prof. R. G. Collingwood calls them, which are of a metaphysical nature, and without which science could not stir an inch? For example, the idea of the uniformity of Nature, the conception of the rationality of things, and the idea of causation itself? Hume long ago claimed to have shown that the validity of the causal relation is not founded in experience, since experience only shows us that one event follows another, and does not exhibit to us the inner necessity of their union. In short, the idea of causation is a hypothesis, rather different from the type of hypothesis illustrated by Sir William Bragg, since science cannot afford to change it, but perhaps not dissimilar from the type of hypothesis, or "absolute presupposition", which religion seems to need.

Of course the man of science is quite justified in taking the idea of causation and other similar ideas for granted; if he did not, his researches into natural happenings would never begin, still less arrive anywhere. And perhaps the mistake the exponents of religion make is not in having metaphysical doctrines, but in placing them on the threshold of religion, where they often prove an obstacle to people trying to enter the house. It may be that Sir William Bragg has this kind of obstacle in mind when he says towards the close of his lecture:

"I am not sufficiently informed to know how all types of mind are affected by the demand for the

absolute acceptance of definite items of faith as a preliminary condition to progress. I believe I can safely say that to many minds this is an impossible demand. Conviction of the truth of any faith, so far as a man can measure the truth, is to be gained by practice, and it is here that the scientist finds an illustration in his own work. Every man, in the circle in which he finds himself, it may be a small circle, his means may be small also, can try the Christian way, and discover for himself and acquire his own convictions. He tests his faith. He has ever in front of him the hope that he will by doing his service play his part in binding the community together."

Speaking of his own youth, Sir William writes: "What we boys asked was the meaning of the word 'believe' when it so often laid down a condition which must be satisfied before a man could be 'saved'. '. . . they that have done evil into everlasting fire. This is the Catholick Faith: which except a man believe faithfully he cannot be saved'. Had we passed the test, or had we not? We were terrified by the threatened consequences. To the youth daily instructed in the need for accuracy and the careful interpretation of words, this was indeed a dreadful saying. If anyone took them at their face value, drew them towards him and explored their significance he would necessarily be driven mad, unless indeed he was deprived of feeling by some drug."

It is a pity that the zeal of the theologian should have converted his "absolute presuppositions" into a barbed-wire entanglement menacing the pilgrim who would explore his temple.

PSYCHOLOGICAL EFFECTS OF AIR RAIDS

By Dr. Robert H. Thouless

University of Cambridge

The experiences of war through which Great Britain is passing pose many psychological problems of urgent practical importance. Knowledge has been gained in many directions which can now be put to practical use. Detailed studies of evacuation, such as the Cambridge Evacuation Survey, the findings of which have recently been published*, enable us to assess both the general success of the evacuation policy and the particular steps which must be taken to avoid failure in special cases. The problems of shelter life have been studied by medical men, by psychiatrists, by shelter lecturers, and by psychologists who have lived in shelters because they have been bombed out of their homes, and it is now possible to gain some idea of the intricate social psychological problems of shelter life. The effects on morale of air-raid experiences have been studied both by academic psychologists and by mass observation, and it is to be hoped that their findings may be made use of by those Government departments responsible for civil morale. These problems were considered at a discussion of the problems of air-raid shelters, evacuation and the effects of air raids at a general meeting of the British Psychological Society on July 26.

Psychologists and psychotherapists have approached the problem of shelter conditions from many different angles; the problems for future research have been clarified and some knowledge has been gained which can be made the basis for practical proposals. The transfer of authority attitudes from within the family to the officials of shelter groups (shelter marshals, etc.) was suggested as an important factor in determining whether defence mechanisms against raid shock would be adequate. It was noticed that a greater sense of security was given by underground shelters than by surface shelters and that the presence of crowds and of the various shelter officials also reduced anxiety. For both of these reasons, individual Anderson shelters were generally neglected and communal underground shelters were preferred. Of those who went to communal shelters, 95 per cent were reported to have got adequate sleep; weight lost at home was regained and neurotic symptoms disappeared. It seems clear, therefore, that the provision of communal shelters rather than of individual ones is, in general, the best policy.

Studies of those who went through air raids as children in the War of 1914–18 showed the importance of adult attitudes of mental calm as a means of protecting children against raid anxiety, and also the reduction of fear by the provision of suitable spontaneous activities. While lectures on such subjects as first aid have been provided for adults and adolescents in some areas,

* The Cambridge Evacuation Survey. Edited by Dr. Susan Isaacs. Pp. ix+236. (London: Methuen and Co., Ltd., 1941.) 8s. 6d. net.

it may be suggested that more effort should be made by those responsible for shelter policy to provide apparatus for suitable activities generally and particularly for children. One area was described in which shelter provision was very inadequate when raids started and a generally apathetic and inert attitude was found among the shelterers. There was little activity ; some knitted, few read. Co-operative activity under a leader did not generally develop spontaneously ; but when a suitable leader was chosen, the amenities of the shelter were greatly improved by co-operative effort. In one shelter, the selection of a good leader resulted in Oxo service, lectures and Christmas decorations, whereas there had previously not been even a broom to sweep the shelter clean.

The problem of the evacuation of children less than five years of age was one that aroused great interest and keen discussion. The general undesirability of evacuating children of this age without their mothers was recognized. On the other hand, it was pointed out that mothers of young children are now often doing war work and that the choice might be between adequate care away from the mother and neglect at home. It was also mentioned that experience at hostels for young children has shown that many of those evacuated from badly bombed areas show neurotic symptoms and unsatisfactory relations with their mothers, and that a period of separation from their mothers in a hostel produces marked improvement in both respects. Some of those present at the meeting consider that a foster-home is more suitable for a young child than a hostel if separation from the mother is necessary or desirable. Other solutions of the problem were mentioned. The Society of Friends has hostels for young children accompanied by their mothers, but these experience the difficulties that have been found in all plans for evacuation of mothers. The mothers do not wish to desert their husbands. A plan that was reported to have been very successful where it has been tried is the provision of nursery centres where children can be left while their mothers are at work. The children may be anxious at first, fearing that their mothers will not return to fetch them in the evenings, but when the experience of a few days proves that this fear is unfounded the children become very happy and contented in the centres. As an alternative to evacuation, this plan suffers obviously from the disadvantage that it may mean that young children remain in danger areas exposed to the risk of physical injury and that this risk must be balanced against the danger of mental injury through separation from the mother.

The general feeling of the meeting seemed to be that evacuation of the mother and young child together is the ideal solution, but that since circumstances might make this impracticable and even in some cases undesirable, psychologists should be prepared to advise alternative methods in particular cases.

One of the defects of the original arrangements for evacuation found in many districts was the lack of provision for those children whose behaviour problems are such as to make them an intolerable burden to the ordinary householder. In many places hostels are provided for such children, but many of these hostels were and still are by no means suitable for this purpose. Some of those present described bad hostels, unsuitably equipped and staffed, where the staff have no idea whatever of the problem child's difficulties or how these might be treated, and where the incidence of certain problems (such as enuresis) is made unnecessarily high by unsympathetic treatment. One speaker described an ideal hostel for treatment at Aylesbury which is housed, equipped, staffed and managed with the aim of relieving the problem child of the burden of his problems. Elsewhere psychological clinics have done excellent work among problem children although the combination of clinic with hostel for treatment appears to be the ideal where practicable.

It is generally felt that a satisfactory hostel is one which makes provision for treatment and is not merely a dumping ground for problem children. There is, no doubt, also a place for the hostel which is merely a clearing house for children who have billeting difficulties, but billeting in such a hostel should be regarded as only a preliminary to treatment. It is felt that psychologists are now in a position to state the requirements of a treatment hostel in equipment and staff, and it was agreed at the meeting that such a statement should be made.

It is not unlikely that the ideal requirements of the social psychologist in provision for problem children will not be met on grounds of expense. It must be remembered, however, that we now have unique opportunities of dealing with the problems of maladjusted children at an early stage and that the provision of reformatories and prisons for the maladjusted members of the community is also a heavy expense to the community.

Investigations in heavily raided areas other than London seem to show that, although morale was in general good, there were failures of morale and a definite tendency for it to deteriorate, particularly in areas which had a number of heavy raids with long periods of calm between them. Deterioration of morale was shown by unauthorized and unnecessary evacuation, general depression about the War, and criticism of the Government. It was interesting to notice that while people in the most

heavily raided areas were more critical and depressed, they were nevertheless more active in A.R.P. work and saved more money than in less raided areas. They were also more inclined to reject the idea that we should undertake reprisal raids on German towns.

The necessity was pointed out of confidence (and justified confidence) in the shelter provided. In some areas shelters have been unsafe, with bad psychological effects. The possibility was pointed out that even where there are no dramatic failures to stand up to bombing (such as psychoneuroses), there might be long-term effects which were little noticed at the time, and that morale might become worse during this winter. It is necessary that there should be propaganda directed towards the strengthening of morale and that psychologists should play a part in the development of a morale policy.

One possible effect of war conditions which has aroused some concern is their influence on the education of children. It is disturbing to learn that, in Glasgow, achievement tests showed that, in one subject (reading), children were on the average about one year behind mean school level. It is also suggested that the situation may be worse in areas which have been raided over a longer period than Glasgow. On the other hand, there must be a considerable proportion of children in reception areas whose education has been relatively little retarded. It seems very desirable that there should be more extensive studies directed towards discovering the amount of educational retardation in different areas and the proportion of children showing marked educational retardation, and if this is found to be generally serious that steps should be taken to prevent the matter from becoming worse. Many of the advantages of universal education and the additional advantages hoped for through a raising of the school-leaving age will be lost if there is continued educational retardation through enemy action.

SOLID CARBON DIOXIDE AS AN EXCITER OF VIBRATIONS

By Mary D. Waller
London (R.F.H.) School of Medicine for Women

It is well known that solid carbon dioxide produces noises or squeaks when it is brought into contact with metal objects such as a hammer or chisel, and so long ago as 1932 the fact that a bicycle bell could be made to emit a chattering ring by touching it with the material was brought to my notice by an itinerant vendor of ice-creams[1]. This strange phenomenon has since been investigated very thoroughly and the results published in a number of papers[2]. As the solid carbon dioxide method of producing vibrations is in certain respects unique and can be applied to various problems, it seems desirable that a short account of it should be put on record.

Production and Maintenance of Pure Loud Tones

When a tuning-fork of ordinary pitch is touched with solid carbon dioxide, a chattering noise is produced. When glass is touched there is no sound. When, however, a fork of say 2000–3000 c./sec. is tried, provided the contact between the two solids is light and the area of contact small, an intense pure note may be produced and maintained for several minutes. The demonstration of this phenomenon is very striking.

Quality of the Exciter. Compressed 'snow' solid carbon dioxide is not satisfactory. A high density 'ice' variety, such as 'Drikold', which is manufactured by Imperial Chemical Industries, Ltd., may be recommended. The material may be conveniently stored for some days in a large thermos flask, and handled with lined gloves or a piece of flannel or tweezers. It may be broken up, so as to obtain suitable pointed pieces, by means of a hammer and chisel.

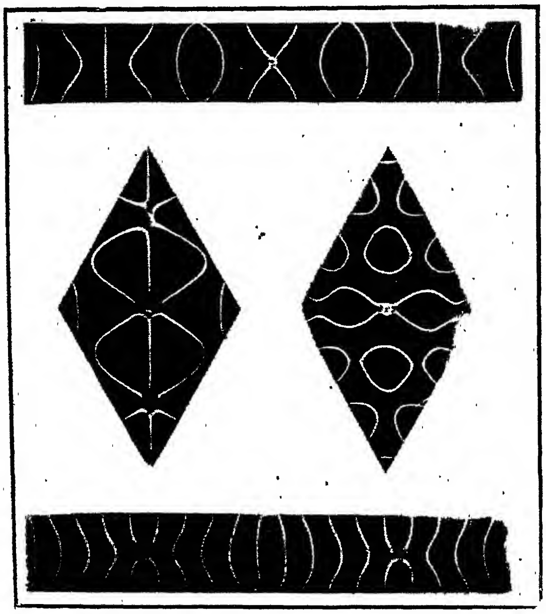
Nature of the Vibrating Object. Tuning-forks, suspended brass bars, tubes, rings and metal plates are easily set into vibration, since they are good thermal conductors and possess adequate vibrating properties (see also below).

External Conditions. The atmosphere must be dry. Excitation may be rendered independent of the hygroscopic conditions by gently warming the vibrating object and surrounding air by means of a bowl electric radiator, care being taken that the heat is not sufficient to alter either the elastic or damping properties of the material of the object.

Manipulation. It is very important that the

pressure between the two solids be very light and the area of contact small, and it is desirable generally to use pointed pieces of solid carbon dioxide. It does not appear possible to substitute a mechanical device for the hand, and the skill of the operator in sensing the onset of vibration, the amplitude of which grows with remarkable rapidity, increases with practice.

The range of frequencies most easily excited by means of solid carbon dioxide lies between about 1000 and 4000 c./sec. and depends but little upon the size, shape, mass, or material of the vibrating object. When objects of low fundamental frequency are touched with solid carbon dioxide, as mentioned above, a rattling noise may be produced,



CHLADNI FIGURES PRODUCED BY SOLID CARBON DIOXIDE

but when the technique described in the last paragraph is adhered to carefully, it becomes possible to excite the overtones which lie in the preferred range of 1000–4000 c./sec.

Mechanism of Production of Vibrations

Solid carbon dioxide sublimes at $-80°$ C. Large pressures are accordingly produced when the material is brought into contact with the warmer metal, due to the formation of gas. The source of energy is the heat which is transferred from the one solid to the other, and the phenomenon may be compared with the Trevelyan rocker, where, however, the vibrations are gravitational, not elastic, and are sometimes slow enough to become visible. The vibrating object, of course, governs the frequency of vibration, and each time the object approaches the exciter it receives an impulse due to the irresistible molecular forces of sublimation which are operative at the moment of contact. Each impulse lasts only a fraction of the total period, when the localized pressure is then very great as compared with that which exists during the rest of the vibration. It is also possible to offer an explanation, in terms of the mean free path of the carbon dioxide molecule, of why the solid carbon dioxide is selective in the matter of the range of frequencies which it will excite[2].

Vibrating Plates

One of the most interesting applications of the solid carbon dioxide method of producing vibrations is to the production of Chladni figures on plates. A few illustrations of the possibilities of the method are given in the accompanying figures and the reader will find numerous others in the papers[3,4], in which the systematic study of vibrating plates of several different shapes are described.

Excitation is very intense and the fact that it can be effected at any point on the surface, and that mechanical pressure (other than that of the gas) is absent makes the method peculiarly simple and effective. Moreover, since the exciter possesses no natural period of its own, no adjustments of frequencies are necessary as in the case of excitation by electrical methods, and the possibility of producing forced vibrations is also excluded. When a divider is used judiciously to fix the position of the nodal lines, any normal figure may be rapidly produced at will. It has been possible, for example, to produce every single one of the fifty-one normal nodal figures of the first six octaves of the free circular plate and to arrange their photographs in a systematic manner on a single diagram. The nodal designs of the square plate have been treated in a similar manner and also those of the right-angled triangular plate[3].

Further Applications

Some of the nodal designs, especially when two normal modes of near period combine, are very beautiful and have been used for decorative designs executed in metal or wood and for embroideries.

Want of uniformity or flaws in plates may be discovered by the distortions in the normal nodal figures which result therefrom. Semi-conductors may be distinguished from insulators, a matter which is of some interest to the geologist. I have actually used the method successfully to find, at short notice, a long-lost quartz lens which had been placed among a large number of glass lenses. Similarly, diamonds and pearls may at once be distinguished from their counterfeits, inasmuch

as the real articles emit a rattle or squeak when touched with solid carbon dioxide.

It is also noteworthy that the object to be excited need not be rigidly supported. Another characteristic is the picking out of single overtones in objects of irregular shape which emit but a jangle of notes when struck with a hammer. This might be applied to find the resonances in either small pieces of machinery or in small-scale models of larger machines.

Finally, looking to the future, it is worth recording that the demonstration of the production of Chladni figures by means of solid carbon dioxide is an excellent subject for scientific television[5] since, while the patterns grow on the screen, the corresponding note is heard by the ear. The success of the demonstration is assured by the dry, warm conditions which necessarily prevail under the fierce illumination necessary for the projection.

CENTENARY OF W. H. HUDSON

BY H. J. MASSINGHAM

W. H. HUDSON, the centenary of whose birth is celebrated this month (see NATURE of August 9, p. 160), was unique as an interpreter of Nature, and that is perhaps the reason why he has had neither followers nor predecessors. The school of modern ornithology and natural history acknowledges no debt to Hudson; its highly specialized activities would, indeed, have been abhorrent to a naturalist who wrote "To specialize is to lose your soul". Its prophets and teachers have been Edmund Selous, Eliot Howard and the biologists, not Hudson. Nor is it possible to trace any line of descent or genealogical tree between him and such great or less dynamic names as John Evelyn, Gilbert White, Dorothy Wordsworth, Edward Jesse, Thomas Miller, Charles Watterton, Frank Buckland, Richard Jefferies, and others, all of whom are to be gathered from the 'herbarium' of the English rural tradition. If we prospect English writers who have immortalized foreign scenes like Bates, Darwin, Wallace, Belt and their kin, we shall find only a superficial resemblance between their works and the Hudsonian corpus of exotic reminiscence like "Far Away and Long Ago", "Idle Days in Patagonia", "The Purple Land", "El Ombu" and "The Naturalist in La Plata". The only exception to so general a statement is perhaps "Argentine Ornithology", written avowedly as a text-book and in conjunction with W. C. Sclater, a professed man of science. But even in this work Hudson is plainly cramped and ill at ease, while his descriptions are constantly flooding the scientific banks of classification and the presentation of strictly relevant data.

On the other hand, the problem of assessing Hudson's place in science or letters or both or neither is by no means solved by assuming, as his fellow and contemporary observers of Nature were inclined to do, that he was first an artist and only secondarily a naturalist. This was an error of the first magnitude. Hudson's contributions to our knowledge of South American fauna and flora were both extensive and profound. To say nothing of his intimate studies of Argentine and Patagonian birds, particularly in courtship, migration, social habits and melody, his masterly discoveries into the living characteristics of such pampa or desert animals as puma, vizcacha, huanaco, dolichotis, semi-domesticated cattle and horses (not to mention the feral Indian and gauchos) alone entitle him to take his place among the chieftains in the hierarchy of natural observation. His original records of English wild life were of scarcely less permanent value and novelty. Instances are numerous—I need only refer to his accounts of *Locusta viridissima* in "Hampshire Days", of such rare species as the Dartford and marsh warblers, of the continued mating of starlings after the breeding season in "Birds in a Village", of the behaviour of shepherds' dogs in "A Shepherd's Life", of the perceptual senses of deer in "A Hind in Richmond Park", to his criticisms of Darwin's theory of sexual selection, and there are at least a score of further examples which reveal Hudson as a pioneer in the investigation of natural phenomena alone.

Yet it is obvious that to claim Hudson for the remembrance of posterity upon no other ground than this is to compass only a fragment of the man. Hudson was essentially a mysterious and paradoxical figure, and this central truth about him gave much handle to misunderstanding both among men of science and the general public. The latter realized his greatness so little as to ignore his enrichment both of science and literature for the first thirty years of his English life after leaving the Argentine. He was compelled to live in London (in the

dingier part of Bayswater) because he could not afford to escape from it into his natural environment, which was the country, and the wilder the better. He was not recognized as of any deep significance in authorship until he was an old man, and then, as he told me himself more than once, when fame and the less straitened means that accrued from it were of little account to him. To the learned he was suspect because he mixed up natural history with religion, poetry, animism, fancy, emotion and the humanities. He would not fit in to the current definition of the arts because of his naturalism and his crusading spirit or into that of scientific analysis because such elements as vision and fantasy were considered irrelevant to it. That is the trouble of being something unique : escaping all the categories, it earns either their hostility or indifference. And it must be confessed that it is difficult to come to terms with a man who is neither one thing nor the other, but both in one, a oneness that is specifically neither.

Nevertheless, I think it is possible to arrive at a true conception of this enigmatic spirit, though without dispelling a certain mystery that clothes him and is part of the mystery of life itself. But only on one condition. It is that we should regard him not as standing apart from Nature and examining its manifestations in the detachment of subject from object, but as a being living and speaking within Nature and in an organic relation with Nature extremely difficult for modern man to comprehend. Withdrawal from Nature is the attitude of modernism, and distance in this instance lends not enchantment but diminution to the view. By looking at Hudson as a kind of human embodiment out of Nature, we are not only enabled to see him more clearly and to resolve the apparent contradictions and antitheses in his make-up, but also to enlarge our own perception of Nature itself, or, as Hudson would undoubtedly have said, of Nature herself.

The most remarkable quality of Hudson as a writer was his articulate primitiveness. This went very deep, and was by no means confined to his habitual and entirely unsophisticated preference for the wildness in Nature. He wrote, if I may be pardoned the apparent antimony, as a richly cultivated wild man, and to an extraordinary degree he shared certain characteristics of primitive man which in the most natural way he embodied into his writings. The animistic tendency is one, closely allied with the mythopœic and with story-telling. Hudson could scarcely write a page without bringing some tale into it, tales not only of fact but also of invention, not only of the concrete, but also of the fantastic, and the curious thing is that his reader is not in the least jolted by their seeming incompatibility. Myth and actuality were strangely blended, and his anthropomorphic bent (heinous to the scientific mentality !) was just as 'real' in him as were his chronicles of animals or peoples, whose bona fides nobody would think of doubting.

Yet in other aspects Hudson was a good deal more modern than the moderns. His vision of Nature—and we are bound to speak of it as such—was consciously pantheistic, often expressing itself in exalted (though always simple) idiom and imagery that remind us of the much more intricate seventeenth-century 'metaphysicals'. His idea of man's place in Nature, utterly contrary to Huxley's, as gathering to a point the joy and exuberance of natural life and through it finding contact with the unseen world, as drinking deep of the life of Nature but observing a royal impartiality towards its phenomena and refraining from interference with its balances and interdependences, this mental approach is a philosophical rendering of a primitive feeling. Hudson loathed all human rapacity towards Nature, but disdained the sentimentalism of reproaching "the cruelty of Nature" in raptorial bird or beast. His mind was entirely estranged from that of civilization because its home was both behind and beyond it.

The Russian lecturer, Nicolas Berdyaev, directs a searching criticism against the modern theory of progress on the ground that it disintegrates time into past, present and future, which are spectral in the sense that each devours the other. Hudson's work is an apt illustration of these three divisions of time in a mutual and non-destructive relation to one another. To Hudson the primitive past was the deepest source of his inspiration, and through it he envisaged a future of the relations between man and Nature which would enshrine their reconciliation. His most famous book, "Far Away and Long Ago", reveals a more personal fusion between boyhood and old age (it was written when he was seventy-six) inexplicable from the point of view of an enkindled memory alone. This minutely detailed record of his childhood on the Argentine pampas is perhaps the most astonishing example of re-animation in our literature. The entire wild scene with its people, its flowers and animals, its effects of light and shade, together with his own sentiments and adventures and reactions, are presented as a living whole with such immediacy that the gaps both of time and space are annihilated. Hudson *senex* evokes a Hudson *puer* not of yesterday, but contained within the present, and there is no other word for this but mystery.

A passage in "The Land's End" illuminates this merging between past and present, boyhood and age, beginnings and ends, the primeval and the more-than-civilized from another and yet stranger aspect. One of a party of grey pilgrims looks over

the sea from the end of all the land, the ancient Bolerium:

"He sees only what his heart desires—a silent land of rest. No person will greet him there, he will land and go up alone into that empty and solitary place, a still grey wilderness, extending inland and upward hundreds of leagues, an immeasurable distance, into infinity. . . . The sky in that still land is always pale grey-blue in colour, and the earth, too, is grey like the rocks, and the trees have a grey-green foliage—trees more ancient in appearance than the worn granite hills. . . . There he will remain motionless and contented for ever in that remote desert land where is no sound of singing bird nor of running water nor of rain or wind in the grey ancient trees. . . ."

This "illimitable wilderness" is antediluvian and post mortem, the beyond and the uncreate; it is the Land's End and it is Patagonia that he loved even better than his estancia-home of La Plata, where the bright birds sang in the peach-grove; it is the goal of age and the longing of youth; it is intensely symbolic and yet an actual scene. It is all these things in one, and it is thus a conquest of time in total opposition to the modern "conquest of nature" and enslavement to a time arbitrarily sliced up into three divisions.

We shall never understand Hudson unless we see him bathed in this mysterious light, unless we look for him within the heart of Nature where the visionary is inseparable from that which is observed, beauty and romance are fused with an objective natural history and where to see, to know, and to feel are a triune experience. Only one link in the chain of integration is missing, and that is the craft of husbandry, where Nature and man meet on equal terms. But the primitive wildness that was the heart of Hudson did not permit him to surmount the last impediment to a final synthesis. Yet in closing the division between natural truth and poetic beauty without doing violence to either, he, the primitive, must surely rank among the very greatest of modernists. The war of aggression against Nature by means of the machine and the combine would have been profoundly antipathetic to both these elements of his complex being.

As a 'stylist' Hudson is impossible to anatomize. His is not a literary way of writing at all, still less has it any affinity with modern cultism in self-expression. He wrote just as he thought, narrated, described, and speculated—namely, as a child of Nature raised to a high degree of self-consciousness. His manner of writing, that is to say, is the natural manner of growth in the plant, of flight in the bird, and of movement in the wind or the sea. There are no spot-lights in metaphor or imagery, nor is there any sense of manufacture in the structure of the sentences. At times a page will be a flat monotone like a dull day; at others like a spring morning, when the dew is on the spray. His argument, whatever it may be, unfolds itself like a vine tendril or a clematis shoot making its unobtrusive way into the sunshine. Or the pace quickens and a tuft of bright-coloured flowers appears on the green background. His style is thus a method of articulation in perfect harmony both with his subject and his own mystical and intuitive contact with the childhood of mankind. The man who identified himself with all creation and through it felt the touch of the unseen conveyed into his writing the sense of a lost world "where the rose has got Perfume that on earth is not", an Adamite paradise of Nature which has haunted the imagination of the more sensitive among men since the days of Hesiod.

OBITUARIES

Prof. A. J. Clark, F.R.S.

By the death, on July 30, of Prof. A. J. Clark, at the age of fifty-five, pharmacology has lost its leading exponent in Great Britain. He was born in Somerset in 1885, went to Bootham School, and obtained one of the first major entrance scholarships in science at King's College, Cambridge. After an unexpectedly brilliant performance in the Tripos, he went as a student to St. Bartholomew's Hospital, London, and took the degree of M.B. in 1910. He worked with Zunz for a time, and then became Cushny's assistant at University College, London. He was professor of pharmacology in Cape Town, and then succeeded Cushny, first at University College, and then in Edinburgh, where he had been since 1926.

During the War of 1914–18 Clark served in the R.A.M.C. as a captain, and was awarded the M.C. During the present War it was natural that he should be appointed physiological and medical adviser to General Headquarters. He went out to France in 1940 as a lieutenant-colonel just in time to play his part in the withdrawal of the British forces.

He married Beatrice Powell, daughter of the late Dr. Hazell of Cape Town, in 1919, and had two sons and two daughters.

Clark's restless energy and wide knowledge were evident both in his work and in his conversation, and were always available for the assistance of his colleagues, but his general knowledge was also great, and his advice was valued by all. He was a member

of the Medical Research Council from 1934 until 1938 and from 1939 until the time of his death.

He was a great experimentalist, and his interests, both in physiology and pharmacology, were so varied that it is difficult to select a representative list of his discoveries. No one else knew so much about frogs' hearts and how to control them, and no one would have thought it possible to extract so much information from them. He found that the action of digitalis was dependent on the presence of calcium. He found that the washings from frog's heart and serum both contained unknown substances which increased the force of the beat. He published important studies of the pharmacology of peptone and of potassium. With Broom he devised a well-known method for the assay of ergotoxine. In 1927 he published a book on "The Comparative Physiology of the Heart", and in 1938 he published another on "The Metabolism of the Frog's Heart", which was largely based on his own work with various collaborators.

Clark's main interest was in the light thrown by quantitative pharmacological experiments on the fundamental problem of how drugs act. He wrote a book called "The Mode of Action of Drugs on Cells" (1933), and a supplementary volume to Heffter's Handbook called "General Pharmacology" (1938), in which he codified a large number of papers in this field. The original authors had treated their results in all sorts of ways, and reached all sorts of conclusions. Prof. Clark replotted, recalculated and tabulated their results by uniform methods. He emphasized the danger of fitting simple curves to observations on complex living tissues by showing that the results could often be equally well fitted by several different simple curves. He cleared the air by demonstrating that "an intensive study of any particular pharmacological action nearly always results in showing it to be more complex than was at first supposed". His wide knowledge provided a very rich mine of examples to illustrate his arguments, which were upheld by many experiments of his own and his students. In all this work he was testing the validity of fundamental quantitative generalizations. He was seldom content with direct empirical observations of the effect of chemical structure on pharmacological action.

Clark's "Applied Pharmacology" was first published in 1923, and six more editions appeared in the next seventeen years. This book, in which particular emphasis is laid on experiments on man, has played an important part in the development of the science of experimental therapeutics; it serves as a link between the laboratory and the ward.

J. H. Gaddum.

We regret to announce the following deaths:

Dr. Frank Haydon, formerly Secretary of Apothecaries' Hall and for many years oculist to the Southern Railway, on August 1, aged seventy-nine.

Dr. A. L. de Morais Sarmento, the well-known Portuguese physician and Rector of the University of Coimbra, on August 11, aged fifty-three.

NEWS AND VIEWS

Sir Robert Robinson: First Paracelsus Medallist

A delightful function took place at the Dorchester Hotel on August 6, when the Swiss Ambassador, in an after-luncheon speech, presented to Sir Robert Robinson, F.R.S., Waynflete professor of chemistry in the University of Oxford, the Paracelsus Gold Medal of the Swiss Chemical Society. This is the first occasion upon which the award has been made, and it is gratifying that the Swiss chemists should recognize in this manner Sir Robert's pre-eminence in the scientific world. His versatility is such that he has enriched every branch of organic chemistry, but it is perhaps as a master of the synthetic method that he has gained special fame. His outstanding gifts in this direction became evident early in his career, when in 1917 he effected a synthesis of tropinone, noteworthy on account of its extraordinary novelty and simplicity. The concept upon which this and other alkaloid syntheses was based was a direct outcome of a comprehensive theory of biogenesis of plant products which was contributed to the Chemical Society in the same year, and which marked an epoch in alkaloid chemistry.

Other outstanding achievements in this field include a large number of inspiring memoirs on the indole group of alkaloids, the morphine group, including a modification of Knorr's morphine and thebaine formulæ and finally the establishment of the correct structures of strychnine and brucine. Robinson's interests have, however, extended far beyond the alkaloid field. One recalls the brilliant work carried out in association with W. H. Perkin, jun., on the constitution of brazilin and hæmatoxylin; from this arose his interest in pyrylium salts, leading to elegant synthetic work on anthocyanidin structures and culminating in the striking achievement of the synthesis of the anthocyan flower pigments themselves, one of the finest pieces of research of our generation. And now another trail is being blazed, this time on the synthesis of steroids and sex hormones; here, as always, with Robinson's work, one is struck by the simplicity and freshness of approach and the ingenuity displayed in building up the required ring-systems. No account of Robinson's work would be complete without mention of his important contributions to the theory of organic reactions, crystallized finally in terms of modern electronic hypotheses relating to the nature of valency bonds. The theory which collates on a common basis a diverse mass of data in organic chemistry, has had an important influence in the development of the science.

Prof. Edgar Allen: Bayly Medallist

PROF. EDGAR ALLEN, to whom the Bayly Medal of the Royal College of Physicians has just been awarded, is professor of anatomy in the Yale University School of medicine, a post to which he succeeded in 1933 after a very fruitful period of office in the University of Missouri. In both universities his department has proved a vigorous centre of research on the sex hormones, and his own contributions to the subject form an essential foundation to modern knowledge of the endocrine action of the ovaries. Before 1917 attempts to isolate ovarian internal secretions were seriously handicapped by the lack of a specific test for what to-day is called œstrogenic action. In that year Stockard and Papanicolaou showed that the œstrous cycle in the guinea pig is associated with cyclical changes in the vaginal epithelium. Shortly afterwards Allen found that in the mouse, too, œstrus is associated with a specific vaginal phase, and from this discovery it was a short step to his and Doisy's successful application of the vaginal smear technique as a test for the œstrogenic action of ovarian extracts. Once extracts with demonstrable œstrogenic activity were made available, the door was open to the chemical isolation, analysis and synthesis of pure œstrogens. Although Allen did not share in this later chemical work, there can be little question that it would have proved impossible without the simple bio-assay method which he developed.

Allen's second major achievement was his demonstration in 1926 of the fact that the follicular phase of the uterine cycle in monkeys and man is under the control of œstrogenic hormone. All later work on the primate cycle emerges from this finding, and Allen's own subsequent investigations have a significant place in the structure of present knowledge of the subject. His contribution does not rest here. Allen is that rare combination of research worker and administrator who is able to stimulate in younger men a strong and lasting interest in research. His laboratory is one of the most productive in the United States, and while the Bayly Medal is a recognition of past work, endocrinologists the world over know that Allen's laboratory will prove no less successful in the future than it has in the past.

Mr. Orville Wright

MR. ORVILLE WRIGHT celebrates his seventieth birthday on August 19. It was he who, together with his late brother, Wilbur, first flew a heavier-than-air machine on December 17, 1903, at Kitty Hawk, North Carolina, and, also with his brother, invented the system of control used in flying machines to-day. The first flight lasted only twelve seconds, but further experiment and trials resulted in the development of an aeroplane which established a new record on September 12, 1908, by remaining in the air for seventy-five minutes. The Wright brothers began their investigations on kites and gliders in 1900. Then they introduced two improvements: (1) the elevator for steering the machine in a vertical plane, which, though now usually attached to the tail, was placed by them in front of the main planes; (2) flexing of the rear edge of the main planes so as to vary the lift on either or both, thus maintaining balance. A petrol motor-driven screw was added in 1903.

The Wright brothers were also great exponents of the use of the wind tunnel in aeronautical investigations. The first motor-driven machine which was used by the Wright brothers in their pioneer flight on December 17, 1903, is now exhibited in the Science Museum, South Kensington. Wilbur died on May 30, 1912. Both brothers have been the recipients of several medals, honorary degrees and other honours. We offer our congratulations to Mr. Orville Wright on the attainment of his seventieth birthday.

Scientific Workers in Industry and Public Affairs

SIR ROBERT PICKARD'S address to the Society of Chemical Industry on the occasion of the presentation to him of the Society's Medal, was entitled "The Influence of Science on National Life", but his treatment of this theme was far less broad than the title. Before 1900, work by Faraday and Playfair, by E. Frankland and Roscoe, influenced the living conditions of the people through their respective investigations on the purity of water supplies and the purification of sewage effluents. Up to then, few research chemists were employed in industry, but between 1914–18 and the present time their number has much increased; and this is also particularly true of the lesser scientific workers (testers, etc.). Science has safeguarded and improved civilized life in innumerable ways; nevertheless doubts and questions have arisen whether the nation makes adequate use of the scientific ability at its disposal. On the whole, Sir Robert is satisfied with the tremendous improvement in such matters that has occurred in the last twenty-five years. Scientific men are not specially competent to deal with certain political and social questions, but they can reasonably claim to be consulted before decisions are made.

Though many of the recent criticisms of the Civil Service seem to Sir Robert to be unjustified, those concerning reluctance to take decisions and lack of foresight in formulating problems, appear to be valid; if so, they are due in part to the cloistered life the Civil Servant has to lead. The same cause may operate among scientific workers employed in industry, and Prof. A. V. Hill's plan of regular interchange between scientific staffs in the civil and municipal services, and in university laboratories, should at least offer a partial remedy. As fellows of the Royal Society are, when elected, nearly all specialists of the highest, but narrowest, type, their services to the nation are most likely to be effective when the problem is entirely novel. We in Britain have "led the field" in applying science to the older industries; in the newer industries, based upon recent discoveries, American scientific workers have made "greater bulk endeavours". The modern central research association is also a typically British product, but there is need of reform in current methods of electing directors or heads of such bodies; such heads have in the past been largely "thrown up

by the tide", and we must now seek some method of training the successors of those men who are the present leaders. A head can be a success only if he agrees to cease his work as an expert, after appointment.

Great Britain and the U.S.S.R.

THE British Association has received the following message in reply to a resolution recently forwarded through M. Maisky to the U.S.S.R. Academy of Sciences (see NATURE of August 2, p. 135): "The Academy of Sciences of the U.S.S.R. sends warmest greeting to the Committee for Social and International Relations of the British Association for the Advancement of Science. With the help of scientists of both our countries the united peoples of Great Britain and the Soviet Union will triumph in the war for the liberation of humanity from Fascist tyranny. Otto Schmidt, vice-president, Academy of Sciences of the U.S.S.R."

U.S.S.R. Academy of Sciences: Air Raid Damage

ACCORDING to the British United Press, it can now be revealed that German raiders recently set fire to the library of the U.S.S.R. Academy of Sciences, one of the most famous landmarks in the city. The fire was put out, however, before any of the three million valuable books in the library were destroyed. It may be recalled that the Germans, during the early raids on Moscow, boasted that the Academy of Sciences had been destroyed.

Black-out *v.* Controlled Lighting for Air-raid Defence

THERE has always been controversy upon this subject, and while Britain has adopted the complete black-out in this War, there is a considerable opinion held in the United States that some form of uniform lighting, to disguise landmarks, would be equally effective and less hampering to the inhabitants of the district. Experiments are being carried out, but the problem is not capable of any very precise solution, as the results are entirely dependent upon the personal estimation of the observers from the air. Even in an actual attack, the results of bombing depend upon so many variable factors that it would by no means follow that the concentrated bombing of a certain district was due to its ineffective concealment.

The principal arguments against a black-out are the impossibility of hiding rivers, railways and long, straight roads; fires and enemy agent signals are more obvious; dropping of flares effectively lights up at least a limited area. It adds to the difficulties of all forms of defence and A.R.P. work during an attack, and it hampers all work and social life as it is necessarily applied continuously, since it has been proved that it is impracticable to bring black-out into operation only when an attack is expected. It is claimed that a uniformly spread mantle of light would not make a town any more obvious, and could be made to disguise any particular object equally well.

The difficulty lies in obtaining uniformity, with the different classes of buildings, open spaces with no buildings or roads, and the irregular contour of the city that could be co-ordinated with a map. There is the further problem of enforcing that uniformity when it is attained. Watching the observance of a complete black-out is easier than seeing that a certain standard of illumination from windows, roof lights, etc., is not exceeded. Uniform lighting was used in London and certain other towns towards the latter part of the War of 1914–18, but this was introduced as an alternative to a black-out not nearly so completely worked out or rigidly enforced as the present one. There is also the wider problem of using individual towns as landmarks for navigating purposes. A series of lighted patches, indicating towns, could easily be followed successively with the aid of a map, and made to lead to any desired district. Uniformity of lighting in this respect could only be attained by illuminating the whole country-side—a task of gargantuan magnitude.

Fire Prevention in War-time

MANY of the subjects covered in a lecture delivered to the Royal Society of Arts by Colonel G. Symonds, fire adviser to the Home Office, are of more than general interest. After discussing questions of organization and the need for adequate fire-fighting parties to take immediate action, Colonel Symonds dealt with the 'protective levels' required for resisting penetration by a 1 kgm. incendiary bomb. The figures he gave were: reinforced concrete $2\frac{1}{2}$ in. thick; steel plate $\frac{3}{16}$ in. thick; a paving-stone 2 in. thick with a well-tamped standard sand-bag also gives adequate protection. As regards internal protection, floors can be made fire resisting with 2 in. of sand, $2\frac{1}{2}$ in. of brick rubble passing through $\frac{3}{8}$ in. mesh, or with material conforming to BSS/ARP 27. Less certain protection, but enough to enable a fire party arriving within five or six minutes to cope with the bomb, before floor boards started to burn, would be provided by BSS/ARP 47. Structural timber should be treated with a flame-resisting material. Communicated fire can be stopped by $2\frac{1}{2}$ inch jets supplied with 1,200 gallons of water a minute. Where an 80-ft. space is unobtainable as a fire break, windows facing a lesser gap should be bricked up, or failing this, protected with wired-glass and fire-resisting shutters. An unperforated 14-in. brick party wall with good mortar carried 10 ft. above floor-level on the line of the break will often stand up well to a 'near miss'.

Biochemistry at the Franklin Institute

THE Biochemical Research Foundation Laboratory (formerly the Cancer Research Laboratories), under the direction of Dr. Ellice McDonald, has recently moved from Philadelphia, Pa., to Newark, Delaware. The buildings at Newark are new and specially designed for the work of the Foundation. One wing insulated from the main rooms contains a cyclotron for preparing radioactive substances for use in medical and biochemical problems. The laboratories

appear to be admirably equipped for research in physics, physical chemistry and biochemistry. Miss G. E. Woodward is still carrying on with her researches on the metabolism and structure of amino acids. In this new institute it is expected that close co-operation between chemists, physicists and biologists will lead to new advances.

Rapid Black-out of a Factory

A DESCRIPTION is given in the *Electrical Review* of July 11 of a method of almost completely blacking-out in a few seconds a factory by simply pressing a button. A camouflage installation recently completed at a large factory provides for blacking out 550,000 sq. ft. of roof lights in 15 sec. Originally hard wall-boards were fitted to the outside of all the north lights and other windows. Alternate panels have been removed from the north light windows and fixed into a frame in their respective positions over the windows, the frame being made to move laterally across the whole span of lights through grooves cut in the sections fixed to the glazing bars. Steel cables were fixed to each end of the frame, passed over spring-tensioned pulleys and secured to a winch mounted on the wall inside the factory. The winch is operated by a ¼ h.p. D.C. compound-wound G.E.C. Witton motor. The forward and reverse movements of the shutters are obtained by reversing the direction of the motor, which is controlled by forward and reverse contactors operated by two limit switches. The latter are tripped by 'fingers' mounted on steel rods secured by the cables, which travel up and down through a distance equivalent to the movement of the steel frame. Each span of lights of approximately 1,000 sq. ft. is operated by one ¼ h.p. motor, and more than 500 motors have been installed. In the event of damage to the electrical equipment, the motors can be disconnected and the winches operated by hand in each individual bay.

New Tone for Dial Telephone Systems

IN long-distance telephony when messages or signals have to be transmitted simultaneously over wire networks, an error in dialling may result in reaching a group of numbers not assigned for service. In such cases a special tone may be used to inform the customer of his error, and this special development in switching is widely used in the Bell System networks of the United States. In the *Bell Laboratories Record* of April, Mr. M. E. Krom communicates a paper giving the development of the 'no such number' tone. The new tone varies continuously in frequency, like that of a siren, alternately rising and falling at half-second intervals. The sound is quite different from any other tone used in the Bell system. At the lowest pitch the fundamental frequency is 200 cycles per second, and at the highest pitch, 400 cycles. Harmonics up to 6,000 cycles are in both tones, and these give the latter a richness not found in single-frequency waves. The tone is generated by a 'relaxation' oscillator consisting of a vacuum tube, condenser and resistance. The tone is amplified by another vacuum tube which raises the level above that of the dial and busy tones. To lengthen the life of the vacuum tubes, the plate circuits are closed only when the tone is required ; the filaments are continuously heated, however, to maintain the circuit in readiness for instant service. During field trials it has reduced circuit-holding time on numbers wrongly dialled and resulted in a higher percentage of correct numbers on the second dialling.

Egyptian Astronomy

HERBERT CHATLEY has given in a paper on "Egyptian Astronomy" (*J. Egypt Archæol.*, **26**, 120 ; 1940) certain conclusions regarding the various figures found in the Egyptian "celestial diagram", of which nearly twenty copies from the Eleventh Dynasty down to Roman times are in existence. The general deductions that have been made about the figures are included under eight categories, but limits of space do not permit any detailed description ; those who are interested in Egyptian archæology will find it profitable to study the paper carefully. It is difficult to discover from reading the account of the constellations, Dekanal Band (the dekans were 10-day stars from the helical risings of which the ten-day week of the Egyptian year was marked), Meta-Dekans, etc., how much astronomical knowledge the Egyptians really possessed. Popular belief credits ancient Egypt with extensive knowledge, but archæological research scarcely supports this view in the realm of astronomy. The records show very little regarding the actual observations of their inventors, and many of them are of a magical or religious nature the object of which was to protect or assist the dead. The author has previously expressed the opinion that the dekanal lists were revised about the beginning of the New Kingdom, about 1600 B.C., and he conjectures that the celestial diagram was invented then as a talisman which concentrated the power of the heavenly bodies into one form.

Mathematical Problems in Seismology

A. BLAKE has recently directed attention to many outstanding problems in mathematical seismology (*Trans. Amer. Geophys. Union*, 1940). The following problems are, more particularly, mentioned : (1) Problems in the theory of seismic waves due to inhomogeneities in the media and other causes, and to new methods available for the study of the interior of the earth. (2) Problems of instrumental seismology including the new strain meter and rotation seismograph. (3) Problems relating to the complexities encountered in determining the response of engineering structures to the motion of a strong near earthquake. (4) Problems of statistical seismology, especially the periodicity problem. In many cases Blake states that seismological calculations may be performed by machines such as the differential analyser and punched card machines.

Concerning strong-motion problems, Blake says that the analysis of the response of a structure into characteristic or normal components satisfying linear equations depends on the treatment of the strain-

energy function as quadratic. But the purpose of investigating the response to destructive earthquake motions requires consideration of strains much exceeding the limits within which Hooke's Law remains valid. According to the author, the linear theory can then only be used as a first approximation and the effects of the various components of ground motion cannot be treated separately. The Rayleigh dissipation function may be important but the case of small damping including the existence of normal modes of oscillation has been encountered in the case of buildings, bridges and tank towers. The paper will act as a signpost towards further progress in mathematical seismology.

Epicentres of the Earthquakes of April 20 and 21

THE U.S. Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the provisional epicentres of two recent strong earthquakes. The first on April 20, 1941, at 17h. 38·3m. G.M.T., had an epicentre near lat. 37° N., long. 69° E., which is in Afghanistan and some 160 miles north of Kabul. The second, on April 21, 1941, at 2h. 54·1m. G.M.T. was near lat. 53° N., long. 166° W. which is in the neighbourhood of the Aleutian Islands. Both these areas are well known to be frequented by earthquakes, the Aleutian Islands area having been particularly active in recent months.

Forestry in Uganda

IN the annual report for the year ending December 31, 1940 (Entebbe, Govt. Printer, Uganda, 1941), the Conservator, after detailing the total areas of forest under control, says that under a reclassification of the forests the area of protection reserves has increased at the expense of production reserves. Except for forty-eight square miles of high forest, all the new areas gazetted were savannah land or bush-covered hills with some gallery forest in the valleys. For those with an acquaintance of local African conditions this reservation of savannah and bush lands is of the greatest significance and the Forest Department may be congratulated on its action. It is not the less disturbing, therefore, to read that "Reconnaissance continued on a reduced scale and there are still some 1,000 square miles in the Eastern and Western Provinces which are known to require reservation. In Buganda the need for reconnaissance and reservations was recognized by Government, but staff was not available to make a start." This question, the inadequacy of staff, has interrupted other valuable work in progress. It cannot but be disheartening to Forest Departments when the Administration responsible are unable to realize that forest property and management differ widely from the short-term (in years) policy with which agricultural lands can be treated. In the general interests of the communities as a whole, especially when more or less directly dependent upon the forests, not even the stresses of an Empire War should be allowed to imperil the future of such forest areas.

The Health of Canada

THE April issue of the *Statistical Bulletin* issued by the Metropolitan Life Insurance Company of New York contains an instructive editorial on the health of Canada in 1940. During the last three months of 1939 and almost the whole of 1940 the mortality record in Canada was very favourable; but it showed some rise in December and the first quarter of 1941 owing to the epidemic of influenza which occurred at the end of 1940. As a whole, however, the standardized death-rate of the Canadian Industrial policy holders less than seventy-five years of age was only 592·1 per 100,000, or 12·1 per cent below the average rate for the five preceding years. Among children the drop in mortality was as much as 30 per cent. The greatest improvement took place in the acute and infectious conditions, while cancer and diabetes showed higher rates than in previous years. The decline in the principal infectious diseases in children, namely, measles, scarlet fever, whooping cough and diphtheria was 43 per cent since 1935–39. For measles and scarlet fever the rate was less than two thirds of the average for the preceding five years, and for diphtheria the 1940 rate was little more than one half of the earlier rate. Whooping cough, with a rate of 5·1 per 100,000 in 1940, or more than that for the other three combined, is to-day the most serious of these diseases of childhood. Diseases of the heart, arteries and kidneys together accounted for more than one third of the mortality. As regards tuberculosis the death-rate for the first time fell below 50 per 100,000, the decline since 1935 being 15 per cent. Child-bearing has become definitely safer in Canada, the puerperal death-rate having fallen to 6·2 per 100,000 in 1940 from 9·0 in the preceding five-year period. Lastly, there was an appreciable decline in deaths from violence.

Public Health in Haiti

ACCORDING to Dr. Rulx Léon, Under-Secretary of State in Charge of the Health Service and Public Assistance, a major concern of the Health Service of Haiti is the lack of adequate drinking-water facilities, which is particularly serious in the capital. During the past year, the Government created a public welfare organization which established several hospitals in different parts of the country. 31,202 cases of malaria were treated in hospitals and Government rural clinics. Dysentery and intestinal parasitism existed in endemic form. Outbreaks of measles, ringworm and influenza were quickly controlled. A mild epidemic of diphtheria broke out in the capital. The principal causes of death were tuberculosis, malaria, enteritis, syphilis and pneumonia. A total of 47,950 births and 12,907 deaths was recorded.

Historical Medicine and Science

UNDER the title of "Medical Miscellany: List A" Schuman's, of 730 Fifth Avenue, New York, have published a catalogue of 150 works of historical medicine and science. Of special interest are Abernethy's Hunterian Oration for 1819, von Behring's early contributions on the specific treatment

of diphtheria and tetanus, anthrax, immunity, etc. (1893), the works of Fabricius ab Aquapendente (1619–20), James Lind's "Essay on Diseases incident to Europeans in Hot Climates" (1792), the Life and Letters of Michael Faraday (1870) and George E. Ellis's Biography of Count Rumbold (1871).

The principal feature in Schuman's List B is the inclusion of nine items concerning Paracelsus, the fourth centenary of whose death takes place this year. These items are a Latin translation of one of his principal works, embodying much of his work on chemical therapeutics (1578), his surgical writings in Swiss-German (1605), English translations of Leonardo Fiorovanti's work (1653), Paracelsus's hermetic and alchemical writings (1894), and his one hundred and fourteen experiments and cures (1652), Franz Hartman's "Life of Paracelsus" (1896), the first edition of Browning's poem (1835) and an early seventeenth-century portrait of Paracelsus from the G. Ritter von Frank collection.

Colour Changes in the Paradise Fish

It is well known that the paradise fish, *Macropodus opercularis*, is capable of changing its colour. Y. C. Chin and J. C. Li (*Peking Nat. Hist. Bull.*, 15; 1941) have shown that such changes can be induced by changes in light intensity, temperature and the environmental colour. Their experiments indicate that in the performance of this reflex the eyes act as the receptors and the melanophores as the effectors. The receptor and effector systems communicate in the medulla oblongata. The melanophore nerves appear to be of two kinds, one concentrating and the other dispersive. The actual changes in the melanophores are brought about by the secretion of neurohumours secreted at the ends of the nerves and these are not transmitted by the blood but diffuse from cell to cell. The authors have attempted to express the results in quantitative terms that will permit of more accurate comparisons in future work.

Sawflies of the Berkhamsted District

Mr. R. B. Benson has given students of Hymenoptera valuable help with his paper "Sawflies of the Berkhamsted District" (*Trans. Herts. Nat. Hist. Soc.*, 21, 177–231; 1940). The work is divided into three parts: (*a*) Introduction, (*b*) List of Species, and (*c*) References.

In (*a*), among other matters, the author compares on a percentage basis the number of species—313—taken in Hertfordshire with the other insect groups which have been collected in the county, but takes care to point out that the results tend to show what groups have been best collected rather than the relative abundance of any one of them. The sawflies head the list with 72 per cent, a figure which on either count speaks much for the energy and untiring patience which the author has brought to the task of collecting these insects. Attention is directed to the fact that the abundance of a species may vary within very wide limits over a large number of years. Zoogeographical and ecological aspects are also discussed. Range of locality in Hertfordshire, frequency of occurrence, times of appearance and food-plants of the species are given. The table of references comprises fifty-five items.

Prof. Olof Hammarsten (1841–1932)

Prof. Olof Hammarsten, the celebrated Swedish biochemist, was born at Norrköping in Sweden on August 21, 1841. He received his medical education at Uppsala, where he qualified in 1869, and was assistant at the laboratory for clinical chemistry and the physiological institute. In 1877 he was appointed extraordinary professor of physiology at Uppsala, where he became professor of medical and physiological chemistry in 1883; he held this post until his retirement in 1906. His chief work was his text-book on physiological chemistry, which for many years stood almost alone as a work of reference and was translated into several foreign languages. He had previously won a high reputation by numerous contributions to biochemistry, including the milk-curdling properties of gastric juice, the behaviour of rennin, the role of calcium in the clotting of milk and blood, the proteins of the blood and the mucous substances in the bile. In 1906 he was the recipient of a *Festschrift* which contained a bibliography of his writings up to 1905. He died on September 21, 1932.

Announcements

Prof. J. C. Drummond, professor of biochemistry in the University of London and scientific adviser to the Ministry of Food, has been elected Fullerian professor of physiology in the Royal Institution in succession to Sir Frederick Keeble.

Prof. C. Lovatt Evans, Jodrell professor of physiology in University College, London, has been elected a foreign member of the Royal Physiographical Society of Lund, Sweden.

At the recent conferring of degrees at the Queen's University, Belfast, the degree of doctor of science was conferred on Bryan A. Toms, of the Department of Chemistry of the University.

The Swedish International Press Bureau reports that a board for the control of incorrect or misleading advertisements of medical preparations has recently been appointed in Sweden consisting of representatives of the Royal Medical Board, the Swedish Medical Association, the Federation of Swedish Industries, the Advertising Association and the Newspaper Publishers' Association.

The next award of the Rolleston Memorial Prize, now worth about £100, will be made in Trinity term, 1942, and graduates or research students of the Universities of Oxford or Cambridge, within ten years from matriculation, are eligible. The prize is given for original research in animal and vegetable morphology, physiology or pathology. Essays should be sent to the Assistant Registrar, University Registry, Oxford, before March 31, 1942.

Reactions of Carboxylic Esters

ALTHOUGH, as pointed out in a recent review[1], acid or alkali catalysed hydrolysis or esterification and, it may be added, alkoxy interchange, usually take place by mechanisms in which the bonds of the alkoxyl carbon atom are not disturbed (mechanism I), the alternative mechanism (II) does, however, occur, and probably to a greater extent than has previously been recognized, when the alkoxyl group R″ has electron-releasing properties.

$$R'CO \mid OR'' \ (I) \qquad R'.CO.O \mid R'' \ (II)$$

This fact was brought to our notice during the preparation of some optically active $\alpha\gamma$-disubstituted allyl alcohols. Whereas in the alkaline hydrolysis of the hydrogen phthalates of a large number of optically active saturated aliphatic alcohols under varying experimental conditions no racemization has ever been observed, the optically pure hydrogen phthalic esters of the substituted allyl alcohols, when submitted to hydrolysis with only a slight excess of alkali, yield the partly racemized alcohols; when larger proportions of alkali are used optically pure alcohols are obtained[2]. Mechanism (II) implies dissociation of the ester into a carbonium cation and an anion. If the cation is mesomeric, as it is in the esters of the substituted allyl alcohols, rearrangement is to be expected[1], leading to a mixture of alcohols when mechanism (II) is operative. This has, in fact, been observed: α-phenyl-γ-methylallyl hydrogen phthalate, on hydrolysis by means of a slight excess of 5*N* aqueous sodium hydroxide, yields a mixture of α-phenyl-γ-methyl- and γ-phenyl-α-methylallyl-alcohols[3].

We have further observed that esters of these optically active unsaturated alcohols, when warmed with carboxylic acids or with alcohols, yield esters or ethers with extensive loss of optical purity and therefore, presumably by mechanism (II)[4]. This behaviour is in marked contrast to that of esters of saturated aliphatic alcohols: the hydrogen phthalate of octan-2-ol, for example, can be recrystallized unchanged from hot glacial acetic acid[5]. We also find that esters of phenylmethylcarbinol and of the naphthylmethylcarbinols react in a similar way with acids and with alcohols; we have not, however, observed the occurrence of racemization during the alkaline hydrolysis of the hydrogen phthalates of these carbinols.

The powerful electron-releasing effect of the *p*-methoxyl group causes the above-mentioned reactions to occur very readily with esters of anisylmethyl- and anisylphenylcarbinols. These esters, moreover, are easily decomposed, yielding *p*-methoxystyrene and $\alpha\alpha'$-di-*p*-methoxyphenyldiethyl ether and $\alpha\alpha'$-di-*p*-methoxyphenyldibenzyl ether respectively. The hydrogen phthalic esters of these two carbinols when warmed with dilute alkali yield the neutral esters (di-anisylmethylcarbinyl- and di-anisylphenylcarbinylphthalate).

All these observations are explainable on the assumption that the esters dissociate according to mechanism (II), and detailed descriptions of the reactions are in preparation. An analogous reaction is the racemization, without any observable evidence of decomposition or side-reaction, of the acetate of octan-2-ol, when heated in acetic acid solution with one molecular proportion of a strong acid (for example, *p*- toluenesulphonic or sulphuric acids). This reaction, which may be due either to dissociation or to a continued series of Walden inversion reactions, is at present the subject of further study.

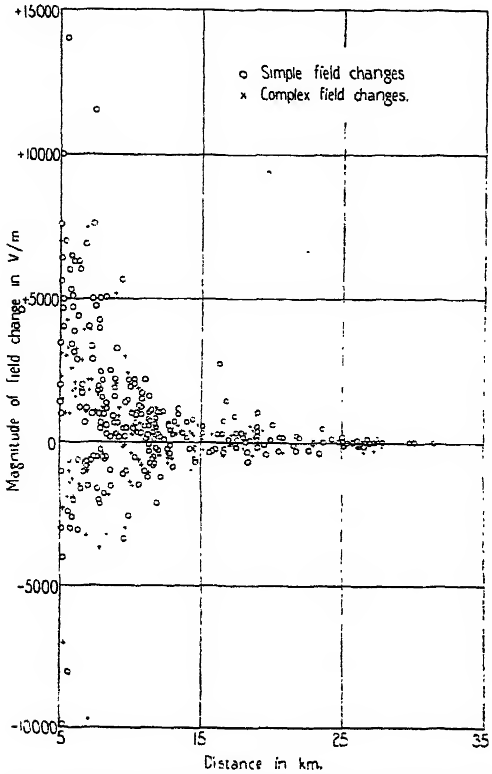
Errors of Observation due to Instrument Scale Limitations

IN the course of a recent investigation of the lightning discharge[1], it was found that scatter diagrams showing the variation with distance of the field changes set up by lightning flashes are liable to misinterpretation owing to a limitation in the recording apparatus which misses all records falling below a certain level. The effect of this limitation has been partly recognized by C. T. R. Wilson[2] in his investigations of the lightning flash, but has been overlooked in later publications on this subject[3]. The misleading effect due to this limitation is demonstrated below, and it is shown that a similar error of interpretation is liable to occur in many other cases in which a statistical analysis is based on data obtained with apparatus having a similar limitation.

The accompanying graph shows as an example the variation of the electrostatic field changes due to comparatively near lightning flashes. The recording electrometer, which was set to reproduce accurately the highest field changes that might be expected from nearby strokes, has a minimum recording limit which, as can be shown, excludes an increasing number of small values as the distance increases. This is shown directly by the fact that, assuming a uniform distribution of flashes, the number of records should from geometrical considerations increase with distance, whereas it decreases rapidly in the diagram reproduced. Again, while the spread of the data at any distance up to about 10 km. shows a ratio of about 50 : 1 between the maximum and minimum values recorded, this ratio decreases to about 10 : 1 at a distance of 20 km., though such variation has no foundation in the mechanism of the lightning



VARIATION OF FIELD CHANGES DUE TO LIGHTNING FLASHES WITH DISTANCE OF ORIGIN (WORMELL).

discharge. Finally, as the distance increases, the mean value shows a definite shift towards higher positions within the distribution of available test records, also indicating that an increasing proportion of the lower end of the distribution is lost.

If it be assumed that the average value at about 10 km. in the graph is correct, the variation of the electrostatic field changes with increasing distance can, as a first approximation, be assumed to vary inversely as the cube of the distance. In the accompanying table, calculated values are compared with the average values derived from the graph.

Distance, km.	10	15	20	25
Calculated, volts per metre	1385	413	175	89
From graph, volts per metre	1385	495	285	125
Appleton and Chapman, volts per metre	700	210*	88*	45

*Interpolated.

The table also includes field changes due to individual lightning strokes from Appleton and Chapman's observations[4]. As a first stroke of a multiple flash causes about one half of the total field change, it will be seen that the agreement of the latter with the calculated values is quite good, while the graph gives values which become increasingly too high as the distance increases.

Similar considerations probably apply to the observation of the variation of other radiation phenomena with distance, and the same fundamental difficulty will also arise elsewhere. For example, the attenuation of surges during their propagation along high-voltage transmission lines was first studied experimentally[5] by recording the amplitudes of surges due to lightning strokes at various points along such lines by means of the klydonograph. Whereas this method produces correct results for surges which show measurable amplitudes at more than one recording point, other surges which attenuate so quickly as to fall below the recording level of the instruments used at the second recording point will be neglected, and their omission will tend to suggest a rate of attenuation which would be too small if all waves had been taken into account. Later investigations with artificial surges confirm that the rate of attenuation as derived by the method described above was too small.

Still greater difficulties in the interpretation of test results are encountered in the determination of the average breaking strengths of insulating materials in a pendulum-type impact testing machine. In such tests, for which, as a rule, only a few specimens are available, the energy to be measured is that which is absorbed by the specimen when it is completely fractured. If the amount of energy absorbed is only a small fraction of that stored in the pendulum, it may be too small to be measured with the desired accuracy and the result is neglected. The same procedure is adopted if the energy of the pendulum is too small to produce fracture of the specimen. It is obvious from what has been said above that these omissions introduce an error in the determination of the average breaking strength additional to those already recognized[6].

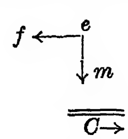
A Relation between 'Motional' and 'Transformer' Induction

THE experimental facts about the action of electric currents on charges may be represented, with some mnemonic advantage, by the accompanying diagram.



C is a current of electrons, e a single electron in or out of a metal, m its direction of motion (which may be all round the clock), f the direction of the force on it due to C, when C is steady. When C is accelerating, e experiences a force in the same direction as if it were moving towards C.

The following remark by Cullwick[1] will be generally agreed to: "It would naturally be very satisfying if the two methods of inducing an e.m.f. could be shown to be particular cases of one general law, but

attempts to do this make use of philosophical speculations which are outside the realm of what is physically definable."

Now, the point in common between motion towards C, and increase in velocity of C, is increase in the angular velocity of an electron in C about the electron e. If v is velocity of the C electrons, and r the distance of e from the nearest element (charge q) of C, $d(v/r)/dt$ positive represents motion towards C, and we may write

$$F = -qe\frac{d(v/r)}{dt}.$$

For v constant, $F = \frac{qev}{r^2}\,dr/dt$, which is Ampere's Law.

For r constant, $F = -\frac{qe}{r}\,dv/dt$, which is Neumann's Law.

It would be interesting to know whether this relation has been already noted. If it could be generalized further to include motion of e parallel with C, the general law covering all forms of induction could be stated without any hypotheses concerning modes of action at a distance.

Mechanics of a Flagellum

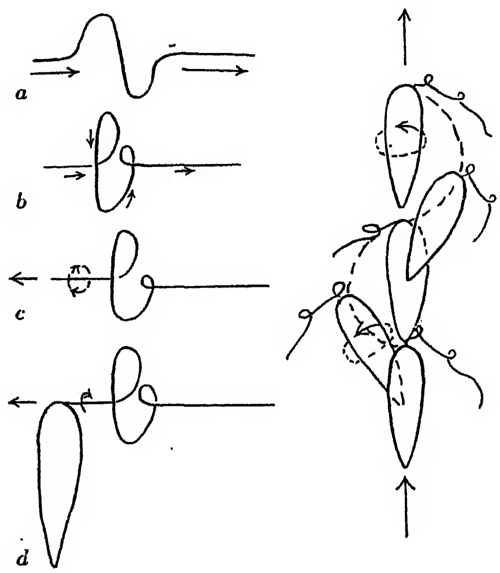
CONSIDER a simple homogeneous filament with a wave passing in the direction indicated and suppose that the filament is immersed in water (a). Allow also that the wave is passing along the filament with both an increase in velocity and amplitude and hence an increase in resistance from the water. It is then obvious, I think, that the wave must take up the form indicated (b). Thus the wave will pass along the filament with rotation in a clockwise or anti-clockwise direction. Let it be assumed that the rotation is anti-clockwise.

We are not concerned here with the nature of the force producing a wave, but that due to the wave acting on the water can be resolved into two components acting in different planes. The greater of the two forces will be one which would tend to force the filament to the left while the other would be acting in a clockwise direction with the main axis of the filament as its centre (c).

Now if we consider the filament to be a flagellum attached to a single cell such as that indicated (d) the one (the main) force of the flagellum would tend to push the attached end of the cell to the left while the other would tend to push the same tip of the cell below the plane of the surface of the paper. If, however, the inertia of the cell were greater than that of the distal end of the flagellum the effect would be to raise the greater part of the flagellum above the plane of the paper instead.

The continuous effect then of a series of waves passing along the flagellum at regular but frequent intervals would be to cause the tip of the cell to gyrate and rotate slowly as indicated in the diagram e, but it is obvious that the frequency of the waves passing along the flagellum must be high compared with the rate of rotation of the cell.

Now the following data have been obtained for *Euglena viridis* by means of high-speed cinema-photomicrography and direct observation. (1) The organism rotates about once per second. (2) Waves pass along the flagellum from base to tip at a frequency of 12–13 per second. (3) As the organism swims forward its anterior end gyrates and traverses a relatively large circle or spiral during the period of a single rotation. Contact prints showing flagella in motion were published in NATURE, 136, 210 (1936). The flagellar movement of several monoflagellates and biflagellates has been diagnosed in the same way, and the paper containing a full description of the method and results has been accepted for publication by the Zoological Society of London.



It is commonly assumed that these monoflagellates possess a *tractellum* or a flagellum in which the waves start at the tip and travel towards the base and thus draw the organism through the water. There seems to be no concrete evidence of the existence of such tractella.

Prevention of Seed-Borne Diseases in the Flax Crop

FURTHER to references[1,2] already made with regard to the prevention of seed-borne diseases in the flax crop, it may now be stated that the seed disinfectant RD.7846 prepared by Messrs. Imperial Chemical Industries, Ltd., and containing tetramethylthiuram disulphide as its active constituent, has been named 'Nomersan'. Through the good offices of Messrs. Imperial Chemical Industries, Ltd., and Messrs. Plant Protection, Ltd., 'Nomersan' was made available in bulk for the dressing of flax seed sown in Northern Ireland in the present season, and upwards of two thousand tons of seed were treated. Disinfection machines of the Strickland pattern were found to be very suitable for the continuous treatment of seed in large quantities, and machines of this type were used throughout the work.

No difficulties were experienced generally with the use of 'Nomersan', although in very occasional cases the powder caused some skin irritation when coming into continual contact with the faces and hands of the workers. During sowing operations when hand machines of the 'fiddle' type are used it is expedient for the sower to wear goggles in order to protect his eyes from the powder. This is of particular importance in windy weather, as the powder is apt to cause general eye discomfort, which is increased if the eyes are rubbed. Normally, it is of short duration and soon passes off.

A considerable quantity of seed was treated by the short-wet method using 'Ceresan U.564' as the disinfectant. For this purpose the 'Kontramix' machine was found to be quite satisfactory for the continuous treatment of seed in bulk.

Up to the time of writing, the crops from seed treated by either method are in good condition and no phytocidal effect has been noted.

Examination of Burnt Documents

IN present circumstances, the examination of documents recovered from receptacles which have been exposed to intense heat has become a matter of some importance, which has already been referred to in NATURE[1]. Many of these burnt documents have been incinerated at a high temperature in the virtual absence of oxygen and can better be described as 'carbonized' than as 'charred'. Such documents do not necessarily behave in the same way as specimens produced in the laboratory by incineration in air.

Carbonized documents are usually fragile, and those which are submitted for examination are presumably of value. It is a safe rule, therefore, to regard each document as a fresh problem in itself and to employ photographic methods of examination to the exclusion of any treatment which might damage or destroy the specimen.

I have, however, been employing a method for the treatment of carbonized documents written in ink, which appears safe and to give such good results as to merit its wider trial. It has been successful where other methods, including infra-red photography, have shown little if any trace of the writing. The method was devised by Superintendent Cherrill of New Scotland Yard and is published by permission of the Commissioner of Police of the Metropolis.

As I use it, the method consists in placing the carbonized sheet upon a glass plate in the bottom of a clean photographic dish and pouring over it a 5 per cent aqueous solution of silver nitrate. A second glass plate is lowered into the solution by one edge so as to exclude air bubbles. If the sheet is distorted, or especially fragile, it may be protected from the weight of the top plate by two glass rods placed parallel to the sides of the sheet. The dish should be protected from direct sunlight. Within about three hours the writing should be clearly visible as a black image against a grey background and is best photographed while the sheet is in the solution. The result obtainable, in contrast with that given by infra-red photography, which exhibits but little more detail than is visible to the eye, is shown in the accompanying illustrations. For permanent record the sheet may be rinsed in several changes of distilled water and then dried rapidly.

Where the original writing is faint, a weaker solution of silver nitrate may be employed, but it should then be allowed to act longer.

The method is simple and has the advantage of bringing up an image which is visible to the naked eye. It has been tried upon a limited number of printed documents (one die-printed letter heading and a number of letterpress printed bill headings) with positive results. It does not seem to be applicable to carbonized typewritten documents, and, since it would appear that the image may be produced by the reduction of nitrate silver, it is possible that the method is applicable only to those documents which have been printed or written with an ink containing a metallic constituent having reducing properties after incineration. Such inks would include the blue-black writing inks, and printing inks containing metallic driers.

CARRIER WEIGHTS OF CONJUGATED PROTEINS

By Dr. E. E. Broda and Dr. C. F. Goodeve, F.R.S.

University College, London

It has recently been observed[1] that the carrier weights, that is, the weight of protein carrying one gram-equivalent of prosthetic group, of a class of conjugated proteins, the chromoproteins, is in many cases equal to the Svedberg unit of about 17,600 gm. In no case is it appreciably less. Data for various conjugated proteins have since become available, and are shown along with the previous data in the accompanying tables. References for the latter data are given in the previous paper[1]. The carrier weights given include the weights of the prosthetic groups, and are therefore too high. The latter are, however, mostly unknown, but as they are certainly comparatively small (4 per cent in hæmoglobin, 1 per cent in the flavins) this error is not serious; moreover, the same systematic error is incurred in calculating the Svedberg unit from ultracentrifugal molecular weight determinations.

The new data confirm that the Svedberg unit is the lower limit of the carrier weights. Moreover, the tables show strikingly that all sufficiently well-defined compounds have carrier weights close to simple multiples of the unit, the 'permitted' carrier weights having the same values of the multiples, namely, 1, 1·5, 2, and probably 4, etc., as Svedberg[13] found for molecular weights. On account of their lower accuracy, conclusions concerning higher multiples appear premature. The existence of Group 1·5 is of especial interest in view of the fact that gliadin and hordein, two simple proteins, have molecular weights of 1·5 Svedberg units. These relationships provide new experimental evidence, *quite independent of molecular weight determinations*, to show the importance of the Svedberg unit.

CARRIER WEIGHTS (NUMBER OF GRAMS OF PROTEIN PER GRAM-EQUIVALENT OF PROSTHETIC GROUP).

Substance	Carrier weight R	Chemical nature of the prosthetic group (on which R is based)
GROUP 1:		
Hæmoglobin (horse)*	16,200	Hæme
Myoglobin (horse)*	16,200	An Fe compound
Erythrocruorin (Cyclostomata)	17,500	An Fe compound
Cytochrome C (horse, ox)*†	16,400	An Fe compound
Hæmocuprein (ox)*	18,700	A Cu compound
Hepatocuprein (ox)	18,700	A Cu compound
Laccase (*Rhus succedanea*)[2]	18,700	A Cu compound
Carbonic anhydrase (ox)[3]	19,800	A Zn compound
Carboxylase (yeast)[4]	18,700	A Mg compound
Thyroglobulin (man)[5]	18,100	An I compound
Average carrier weight: 17,900. Mean deviation from 17,600: 6 per cent. Greatest individual deviation: 12 per cent.		
GROUP 1·5:		
Hæmocyanin (*Helix pomatia*)	25,900	A Cu compound
Hæmocyanin (*Busycon canaliculatum*)*	25,900	A Cu compound
Hæmocyanin (*Octopus vulgaris*)*	25,400	A Cu compound
Hæmocyanin (*Loligo pealei*)*	24,400	A Cu compound
Conjugated protein (tyrosinase ?) from *Lactarius piperatus**[6]	24,500	A Cu compound
Average carrier weight: 25,200. Mean deviation from 1½ × 17,600: 4 per cent. Greatest individual deviation: 8 per cent.		
GROUP 2:		
Hæmocyanin (*Limulus polyphemus*)	36,700	A Cu compound
Hæmocyanin (*Homarus americanus*)	34,000	A Cu compound
Hæmocyanin (*Dromia vulgaris*)[7]	37,400	A Cu compound
Average carrier weight: 36,000. Mean deviation from 2 × 17,600: 5 per cent. Greatest individual deviation: 6 per cent.		

* Crystallized preparations.
† See, however, Theorell, *Science*, **90**, 67 (1939).

CARRIER WEIGHTS OF HIGH VALUE OR OF POORLY DEFINED COMPOUNDS.

Substance	Carrier weight R	Chemical nature of the prosthetic group (on which R is based)
Visual purple (frog)	< 26,500	(from photosensitivity)
Polyphenol oxidase (*Agaricus campestris*)	< 21,200	A Cu compound
Polyphenol oxidase (potato)	ca. 31,800	A Cu compound
Ascorbic oxidase (squash)[8]	< 41,000	A Cu compound
Phycocyan, Phycoerythrin	ca. 30,000	Phycobilin
'Old' yellow ferment*	70–80,000	Phosphorylated flavin adenin dinucleotid
Heart flavoprotein (pig)[9]	70,000	do.
Amino-acid oxidase† (sheep kidney)	< 87,000	do.
Milk flavoprotein[10, 11]	140,000	do.
Catalase (beef liver)[12]*	124,000	Hæme
Ovoverdin	144,000	Astaxanthene

* Crystallized preparations.
† Calculated below.

The molecular weight divided by the carrier weight obviously gives the number of prosthetic groups per molecule of protein. This may vary over a wide range; it is unity for cytochrome C and some of the flavoproteins, 4 for hæmoglobin, about 40 for thyroglobulin and 240 for hæmocyanin (*Helix pomatia*), etc. Clearly it must not be less than unity. On this fact was based an early method[14] of calculating minimum molecular weights of proteins long before the Svedberg unit was discovered.

Carrier weights of conjugated proteins, which dissociate into protein and prosthetic group, can be calculated for the state of suppressed dissociation. For example, for amino-acid oxidase the experiments of Warburg and Christian[15] can serve as a basis. The enzyme activity of the solutions containing varying quantities of protein and prosthetic group is proportional to the bound prosthetic group only. The activity of a solution containing $5 \cdot 4 \times 10^{-11}$ mol of the prosthetic group and a large excess of protein, that is, of a solution where practically the whole of the prosthetic group was bound, was 1·76 units, or $1 \cdot 76/5 \cdot 4 \times 10^{-11}$ units per mol. In another solution containing 2×10^{-5} gm. of protein and a large excess of prosthetic group, that is, in a solution where the protein was saturated with prosthetic group, the activity was 7·51 units and this solution must therefore have contained $\frac{7 \cdot 51}{1 \cdot 76} \times 5 \cdot 4 \times 10^{-11}$ mol of bound prosthetic group or 1/87,000 per gm. of protein. The carrier weight is therefore 87,000. As according to Warburg and Christian the protein was not quite pure, the true carrier weight may well come down to the value for the 'old' yellow ferment, that is, 70–80,000. An independent confirmation is provided by the result of Negelein and Brömel[16],

who found that reduction of the prosthetic group by alanin (which stops as soon as the bound prosthetic group is reduced because the reduction product sticks to the protein) proceeds only until one mol per 100,000 gm. of the (not quite pure) protein has reacted.

ETHNOLOGY OF THE LAU ISLANDS, FIJI

THE great interest held by the Lau islands for the ethnologist lies in the fact that they are situated between Fiji and Tonga, on the border where Melanesia and Polynesia meet. They had been subjected, therefore, to different impacts, both physical and cultural, even before the advent of Western civilization. For this reason the author of a recent paper* chose a group of islands in southern Lau which owing to its isolation and lack of valuable natural resources had been left comparatively untouched by Western influences, and on one of these, Kambara, she lived for five months making an intensive study of its culture. Owing to lack of time she was unable to devote much attention to material culture and concentrated rather on the social system as being more evanescent.

After a short account of the physical types and the geography of the island group, including a census of the chief village of Kambara, the author gives a full description of the social organization of the people. This is very complicated owing to the different influences that have impinged on the islands, but she has worked out the different social groups. The largest unit, the phratry, consists of groups of clans with the same mythical ancestor or group of ancestors. The clans are divided into subclans and these again into families or households. Through all these runs a deep-seated and elaborate system of rank ; not only each phratry, clan, subclan, family and individual, but also each village and chiefdom holds a different rank in the scheme. This is all clearly set out, and in subsequent sections marriage and relationship are discussed, followed by an account of the ceremonial usages and the economic life and material culture of the islands. The author also found time to excavate some archæological sites, principally fortresses on the various islands.

In her conclusion the author suggests that Lauan culture consists of three complexes : that of its own aboriginal (Melanesian) inhabitants, which is similar to that of the low Fijian culture of western Viti Levu. Some three hundred years ago, according to genealogies and tradition, a group of immigrants from eastern Viti Levu introduced a highly organized culture of a Polynesian type with a complicated system of rank, and they also increased production and developed industry to a high degree. The third impact came from the west with Tongan contact in the late "prehistoric" period. Its outstanding contributions were the concept of divine chieftainship with attendant ceremonial, of kava drinking and dancing, while on the material side came the introduction of the western Polynesian oval house and the technique of pasting tapa into long sheets. Thus Lauan culture is truly marginal and presents a unique fusion of Melanesian and early and late Polynesian complexes.

The bulletin is illustrated by maps, tables and photographs, and contains a bibliography and complete index.

SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES

ANNUAL CONGRESS

THE South-Eastern Union of Scientific Societies has, for the second time, been obliged to curtail its annual congress to a single day of sessions and excursions ; this was held at Kingston-upon-Thames on July 26.

A representative assembly to transact the business of the seventy constituent societies was held during the forenoon, in the Queen Elizabeth Grammar School. Dr. W. E. St. Lawrence Finny, who has been mayor of the Royal Borough of Kingston no fewer than seven times, was elected president for 1941–42 ; in recent years he has served the Union as president of the Archæological Section.

"The Church of the Saxon Coronations at Kingston" was the title of Dr. Finny's presidential address. He described the ancient form of the Coronation Service, tracing its origin to the Court of Charlemagne, and showed lantern slides of such evidence as now exists of the church in which the Saxon kings must have been crowned. At Kingston the principal

exhibit is the original Coronation Stone of which the early history is unknown, but a coin is preserved showing Dubnovilaunus, a king of Kent, seated upon a stone of similar size and shape. Another local relic is a fragment of a Saxon commemorative cross bearing an interlaced design of a type not found elsewhere south of the Midlands. In the Lady Chapel of the Coronations there used to be fourteenth-century paintings of five of the Saxon kings crowned at Kingston as well as one of King John: it was the latter who gave the first extant charter to Kingston, the oldest of the three 'Royal Boroughs'—the other two being Windsor and Kensington. The original paintings upon wooden panels of these kings were accidentally discovered in 1813 during the renovation of Baston Manor House in Kent. One of these panels is now preserved in the hall of the Society of Antiquaries, and its Latin inscription gives conclusive proof that Athelstan was crowned at Kingston.

Dr. Finny's address had been preceded by separate sessions for business and the reading of sectional addresses, which will appear later in an abbreviated volume of the *South-Eastern Naturalist and Antiquary* (vol. 46).

The address to the Archæological Section was given by Edward Yates, on "The Early History of Hampton Court Palace". A feature of the Palace is the ease with which the buildings can be dated by the character of the brickwork and fenestration. The address to the Botanical Section was given by Dr. J. Ramsbottom, who spoke on "The Preservation of our Flora". The address to the Geological Section was delivered by Dr. R. L. Sherlock on "The Red Rocks as Indicators of Past Climates". In view of the Thames swan upping having been completed at Henley the previous day, it was appropriate that the presidential address to the Zoological Section should be by N. F. Ticehurst, upon "The Mute Swan on the Thames", illustrated with lantern slides of the old local swan-marks and upping ceremonies. Owing to lack of time, some further papers were taken as read. The Zoological Section papers had been prepared in the form of a *Bulletin* (No. 76). It includes a short paper by Miss Z. V. Waloff, of the Imperial Institute of Entomology, on "The Migratory Locust in the British Isles" and a "Preliminary Note on Dragonfly Migration" as an appendix to the annual report of the Insect Immigration Committee. The latter showed that the regular migration was upon a small scale comparable with that of 1937, and with a similar invasion of the large white butterfly, *Pieris brassicæ* L., the subsequent larvæ of which did considerable damage in market gardens (see *Entomologist*, 74, 54–62).

Dr. Finny conducted a party to Lovekyn's fourteenth-century chantry chapel and to other places of local antiquarian interest. Geologists went to Mickleham to examine fresh exposures in the Chalk recently cut for the Dorking by-pass road; a junction of the Middle and Upper Chalk here exhibits fossils of the *Terebratulina lata* and *Holaster planus* zones. R. V. Melville described the history of the Mole Gap and showed a fine swallow-hole near Mickleham Church.

No definite arrangements for the 1942 Congress were announced; but, in view of its jubilee, it was suggested that a suitable centre for an abbreviated Congress would be the Haslemere Educational Museum.

WORLD MAGNA CHARTA

THERE could scarcely be higher tribute to the dramatic instinct and imaginative insight which led Mr. Churchill and President Roosevelt to choose the Atlantic for their historic declaration of peace aims than the fact that German commentators have already recognized and sought to minimize the parallel with the Fourteen Points. They at least have seen that this is no mere declaration of peace aims. It is a moral offensive which strikes Germany in one of her fundamental weaknesses—the dread and certainty of impending disaster.

Unsatisfactory as have been some of the recent debates on propaganda or political warfare, and slight the evidence that the Government was really alive to the value of the 'fifth arm' and prepared to integrate it into the general stragegy of the War, this master-stroke of the meeting and Declaration of the Atlantic provides convincing evidence that the important contribution to British defence and British strategy made by the Prime Minister in his speeches and broadcasts is now recognized. As a statement of peace aims, more could not be expected than is contained in the Declaration; less would scarcely have satisfied the bulk of those who were demanding a declaration of peace aims. Much more important, this clear enunciation of principles derived directly from the President's formula of the four freedoms is the starting-point for a moral and political offensive that will lead to the accelerated disintegration of Nazism. The peace offensive and initiative have passed into Anglo-American hands.

There have indeed already been welcome signs in recent speeches by Mr. Eden that in the field of political warfare Great Britain is no longer to remain on the defensive. In his speech at Leeds on July 6, Mr. Eden declared emphatically that the Government is not in any circumstances prepared to negotiate with Hitler at any time or on any subject. We would intensify our war effort until he and all he stood for was utterly destroyed. In the House of Commons a month later, on August 6, Mr. Eden reiterated the distinction between the military and the economic treatment of Germany. Every recourse that can be devised must be taken to see that Germany does not for a sixth time plunge Europe into war. There could be no wavering on that point although it would be to our disadvantage and to Europe's disadvantage that Germany should be economically ruined after the War. Mr. Eden went on to indicate that the Government had made certain changes in the work

for the co-ordination and for the operation of our political warfare, and that we were entering on a period of greater opportunities in this field.

The eight points of the Declaration made by the President of the United States and Mr. Churchill, representing His Majesty's Government in the United Kingdom, are as follows :

First, their countries seek no aggrandizement, territorial or other.

Second, they desire to see no territorial changes that do not accord with the freely expressed wishes of the peoples concerned.

Third, they respect the right of all peoples to choose the form of Government under which they will live ; and they wish to see sovereign rights and self-government restored to those who have been forcibly deprived of them.

Fourth, they will endeavour, with due respect for their existing obligations, to further enjoyment by all States, great or small, victor or vanquished, of access, on equal terms, to the trade and to the raw materials of the world which are needed for their economic prosperity.

Fifth, they desire to bring about the fullest collaboration between all nations in the economic field, with the object of securing for all improved labour standards, economic advancement and social security.

Sixth, after the final destruction of Nazi tyranny, they hope to see established a peace which will afford to all nations the means of dwelling in safety within their own boundaries, and which will afford assurance that all the men in all the lands may live out their lives in freedom from fear and want.

Seventh, such a peace should enable all men to traverse the high seas and oceans without hindrance.

Eighth, they believe all of the nations of the world, for realistic as well as spiritual reasons, must come to the abandonment of the use of force. Since no future peace can be maintained if land, sea, or air armaments continue to be employed by nations which threaten, or may threaten, aggression outside of their frontiers, they believe, pending the establishment of a wider and permanent system of general security, that the disarmament of such nations is essential. They will likewise aid and encourage all other practicable measures which will lighten for peace-loving peoples the crushing burden of armament.

This unequivocal declaration regarding Nazism deals the first blow in the political offensive for which Sebastian Haffner calls in his book "Offensive against Germany". While waging war with all our strength, we are giving it a purpose which makes resistance on the enemy's part superfluous and impossible. The most cursory reading of the Declaration of Mr. Churchill and President Roosevelt, with its reference to the final destruction of Nazi tyranny and the pledge to endeavour, with due respect for existing obligations, to further the enjoyment by all States, great or small, victor or vanquished, of access on equal terms to the trade and raw materials of the world, which are needed for their economic prosperity, indicates how well the opportunity has been grasped.

Here at long last Anglo-American co-operation is fashioning weapons for a moral offensive, perfecting the technique and tactics of effective propaganda. Here is the break with the wavering policy of the last ten years, and the creation of a policy giving full power to propaganda, confronting the misery and slavery of the Nazi New Order with an equally tangible but nobler New Order. Here is the formulation of our cause in terms which should make it an irresistible moral weapon.

No better answer could indeed be given than the Declaration of the Atlantic to Nazi and Fascist attempts to represent the War as a conflict between the large and proper ambitions of young and vigorous races and the unimaginative selfishness of two democracies that have lost the capacity for leadership. The dramatic setting is well calculated to carry the generous spirit of the principles embodied in the Declaration across the frontiers and into the hands of every country that lies under the Nazi yoke. Here is the testimony that Great Britain has accepted the formula of President Roosevelt, that it has turned its back on the world of 1939 and is prepared to make the sacrifices involved in the establishment of the four freedoms and the pursuit of the constructive economic policy by which alone the world can be made free from fear and free from want.

The Declaration does not propose to set up a world in which a man will have a privileged position because he is British or American. On the contrary, in the world contemplated he may be asked to make real sacrifices of national interest or prestige, and from this fact alone the declaration derives immense value, both for the prosecution of the War and for the settlement of the world thereafter. There is nothing in the terms of the document which has not already figured in the speeches of British and American statesmen. President Roosevelt's great speech upholding the four freedoms is not more pertinent in this connexion than the Prime Minister's refusal even in our darkest hour last summer to abate one jot of our commitments to restore liberty to those peoples who have been deprived of it, or Mr. Eden's recent insistence that peace must not bring destitution even to the guilty. It is the formal recognition of such aims and principles, the assumption by the United States and the British Empire of a joint responsibility for all that is implied in the establishment of such a peace, and the definite association with those aims and principles of the destruction of Nazi oppression and the disarmament of the

aggressor nations, and the enactment of measures to secure peace and order while leading ultimately to collective disarmament, which give the declaration the force of high explosive in the hands of friends of liberty in all the oppressed countries.

"Here in Britain," said Mr. Eden, on July 6, "we must lay the foundations of a new Europe, at meetings of the Allied Governments", and the forthcoming meeting will acquire fresh inspiration and value from this demonstration not merely of American association with that task, but also that the Government is imaginatively alive to the possibilities and opportunities of fashioning the future of men's hopes amid the sights and sounds of war. On the wide waters of the Atlantic and this free soil of Britain, the forces of freedom are being marshalled, and the Declaration affords reasonable assurance that the future peace settlement will not fail because it either lacks large and bold economic imagination, or makes too little provision for safeguarding Europe from another outburst of aggression. Not again can Britain and the United States take too lightly their duties of order and peace.

The eight clauses of the Declaration deserve and should receive the closest study. Even at a first glance, their resemblance to principles already enunciated by many responsible studies of the central problem of Germany and European order—as, for example, the conclusions of the recent broadsheet issued by Political and Economic Planning (P E P) on "The Future of Germany"—is as remarkable as the harmony of the whole circumstances in which the Declaration was made with the conditions of a moral offensive, as indicated by Sebastian Haffner, or by Mr. Wickham Steed in recent letters in *The Times*. The hopes the Declaration will inspire in Europe are well founded, because here at last is clear recognition of the twin and inescapable conditions of any true peace—the provision of real incentives to observe it and real deterrents against breaking it.

It has been clear for months past that both in Great Britain and in the United States it is increasingly recognized that the economic foundations of peace are as important as the political, that vanquished and victors will have to live together in the world of to-morrow, and that a rising standard of living, such as a well-ordered world can furnish, will be one of the indispensable guarantees of security and the permanent answer to the more specious elements of the Nazi and Fascist appeal. That is the fundamental conception which has inspired the work of the Leith-Ross Committee, the Willingdon Commission or the agreements in regard to shortages and surpluses concluded last June between the United Kingdom and the Dominions of Australia and New Zealand. Its embodiment in this Declaration, the establishment of freedom from fear and want as a world objective, should give fresh purpose and incentive to all such efforts and movements.

No less emphatic is the fifth clause, affirming the desire to "bring about the fullest collaboration between all nations in the economic field with the object of securing for all improved labour standards, economic advancement, and social security". That affirmation should give fresh heart to the many already concerned in dealing with the technical problems involved, and should lend fresh purpose to the meeting of the International Labour Organisation already contemplated this autumn. The solemn exclusion of arbitrary territorial changes and of territorial and material ambitions from our war aims is reaffirmed, and recognition of the right of all peoples to choose the form of government under which they will live is repeated, as well as the affirmation of our desire to see sovereign rights and self-government restored to those who have been deprived of them.

The means by which these principles are to be translated into practice have still to be worked out, but already much machinery lies to our hand for the task. The Declaration, as already suggested, gives new importance to the meetings of the Allied Governments in London. In that embryonic conception of a free united Europe, of a European cabinet, must be worked out the mechanism by which the choice of form of government for the occupied and enemy territories must be devised, so that the suppression of liberties in one country is never again allowed to threaten the liberties of others. The addition to those meetings of free German representatives from among the many distinguished German émigrés already to be found in Great Britain, parallel with the Free French representatives, might well supply the vital touch, particularly in the formulation of the strategy and tactics of political warfare on the increasingly offensive scale which the Declaration should rightly inspire.

These are but a few of the consequences which should follow from this historic meeting and Declaration. Gratitude to President Roosevelt for suggesting the meeting and to Mr. Churchill for his instant response, and admiration for the dramatic sense and timing of both meeting and Declaration, will not be the less for the further indication it affords of growing Anglo-American co-operation, and of readiness to accept the full responsibilities of world leadership and all that such responsibilities involve. The courage and imagination which have been displayed are the best assurance that the world will not look in vain to Great Britain and America to provide the leadership and resources adequate to establish the world order outlined in this historic Declaration.

BERTRAND RUSSELL ON MEANING AND TRUTH

An Inquiry into Meaning and Truth
By Bertrand Russell. Pp. 352. (London: George Allen and Unwin, Ltd., 1940). 12*s*. 6*d*. net.

BERTRAND RUSSELL is the Picasso of modern philosophy. He has expressed himself very differently at different periods; and in each period he has exerted deservedly great influence and aroused extravagant hostility. That his works have always produced so strong a reaction is partly due to the sharpness and clarity with which they have been written. But this, unfortunately, does not hold good of his latest book, which differs not so much in its subject matter as in its style from anything that he has written before. It deals in a comprehensive, if unsystematic, way with the class of philosophical problems that are conventionally brought under the heading of the theory of knowledge. Many interesting questions are raised by it and ingenious answers suggested. But the argument as a whole suffers from a hesitancy and discursiveness which make it unexpectedly difficult to follow.

Though he is inclined to drop hints about the limitations of empiricism, Russell still in the main approaches his problem from an empiricist point of view. He says that he is, "as regards method, more in sympathy with the logical positivists than with any other existing school," but he rightly rejects the formalist view, which Carnap and others of them have put forward, that no more is ever necessary for the specification of a language than an account of its syntactical rules. He recognizes that if we are to make statements which can be empirically true or false, we require not merely the formal rules which correlate symbols with one another, but also rules of meaning, which correlate symbols with observable facts. His way of making this point is to take, as what he calls his language of lowest type, "a language consisting wholly of 'object words', where 'object words' are defined, logically, as words having meaning in isolation, and, psychologically, as words which have been learnt without its being necessary to have previously learnt any other words." That he is thinking here of words that are defined ostensively is shown by his further explanation that "an object word is a class of similar noises or utterances such that, from habit, they have become associated with a class of mutually similar occurrences frequently experienced at the same time as one of the noises or utterances in question." At the outset he claims for his object language only that it is one among a number of possible languages of lowest type; but this must not be taken to imply that he conceives himself to be engaged merely in a game of language building. For sentences of the object language are apparently supposed to express what he calls basic propositions, where, by a basic proposition, he means one that "arises on occasion of a perception which is the evidence for its truth"; and he holds that these basic propositions constitute the indispensable foundation of all empirical knowledge. They fulfil this function in virtue of their connexion "with certain non-verbal occurrences which may be called experiences"; and the nature of this connexion is, for Russell, "one of the fundamental questions of epistemology". He implies, indeed, that it is for him the essence of the problem both of meaning and of truth.

In the case of meaning Russell falls into confusion through taking it for granted that meaning is a relation which somehow connects a symbol with some sort of object. Thus he assumes that "when a sentence is significant, there is something that it signifies"; but "since a significant sentence may be false, it is clear that the signification of a sentence cannot be the fact that makes it true (or false). It must therefore," he concludes, "be something in the person who believes the sentence, not in the object to which the sentence refers." This "something" he chooses to call a proposition, defining propositions as "psychological occurrences of certain sorts, complex images, expectations, etc." But this whole line of reasoning is surely mistaken. To ask what a symbol signifies is legitimate if what is required is an explanation of the way in which it is used. In the case of any given sentence such explanations may take the form of translating it into other sentences, the meaning of which is assumed to be known, or of describing the sort of situations to which it is conventionally applied. But this course cannot be followed when the question about the meaning of symbols is completely generalized, for the reason that there is no general usage to explain. There is no one thing that all symbols mean.

It is true that the assertion of sentences may be accompanied by complex images, expectations and so on: but it is very misleading to say that these are in any sense what the sentence means. Similarly, it is true that the expression of a symbol which describes a sensible occurrence is usually in some way an effect of the occurrence in question. But this does not justify one's defining the meaning of the symbol in terms of the causal relation, as

Russell is inclined to do. It is an old philosophical fallacy to suppose that a symbol must have some natural connexion with that which it symbolizes, apart from the conventional rules by which its use is determined. The establishment of these rules does, no doubt, depend on physical and psychological factors, which can be investigated; but these factors do not enter into the definition of the rules themselves.

In the case of truth, Russell hesitates between two versions of the correspondence theory, the 'logical' version, according to which propositions are required to correspond with 'facts', and the 'epistemological' version, according to which they are required to correspond with 'experience'. He eventually decides in favour of the logical version, principally upon the ground that it makes it possible to retain the law of excluded middle, whereas he thinks that, according to the epistemological version, propositions which there is no practical means of verifying must be regarded as neither true nor false. Unfortunately he does not make it at all clear what he intends us to understand by 'fact' as opposed to 'experience'. It depends upon his theory of perception, of which no clear or consistent account is given in the book. In the main, he seems to adhere to a causal theory, according to which sense-data, which are absurdly described, in one place, as "states of ourselves", and in another, as being "inside the percipient's head", are conceived to be the effects of physical events which are themselves unobservable. But he does not try to meet the main objection to all theories of this type, which is that the notion of causality has no significant application outside the field of possible experience. Throughout the whole book, indeed, he makes use of causal relations in a surprisingly uncritical way.

The fact is that, while Russell appears to start from an empiricist position, he does not consistently adhere to it. This is shown, among other things, by his analysis of the use of words like 'this' and 'I', which he calls egocentric particulars. His view is that their peculiarity lies not in their meaning but in their causation, inasmuch as the expression of them is the effect of a "minimal causal chain", which, "in this connection, is the shortest possible chain from a stimulus outside the brain to a verbal response". He concludes that words of this kind are "not needed for a complete description of the world", whatever that may be. But this is to assume that the public physical world is in some mysterious way impersonally 'given', and that the question is to fit the egocentric particulars in; whereas in fact it is just the other way round. Epistemologically, it is necessary to start with the individual's private experience, in the description of which egocentric particulars cannot be dispensed with. Russell does indeed recognize this in the case of "our knowledge of other minds", which he treats as a problem of explaining one's knowledge of events that one cannot oneself directly verify. He takes as an example the proposition "you are hot", which he says is roughly equivalent to, "there is a hotness related to my percept of your body as, when I am hot, the hotness of me is related to my percept of my body". He then remarks that whereas "when I am hot, I can give a proper name to my hotness; when you are hot, your hotness, to me, is a hypothetical value of an apparent variable." But this, according to him, is simply a matter of the insufficiency of my vocabulary. "It is a merely empirical fact that I have not sufficient proper names for this purpose."

I believe this answer to be along the right lines, but it will scarcely do as it stands. For if the fact that I cannot directly verify statements about other people's experiences is simply due to the accidental limitation of my vocabulary, what is there to prevent me from removing this limitation simply by inventing new proper names? The answer is that, however inventive I am, the proper names that I add to my vocabulary will always refer to elements of my own and not of anybody else's experience. For the fact that each person's experience is private to himself is logically necessary. It is so, however, only in the sense that it depends upon the conventions that we have chosen to adopt in speaking about people's experiences: and the facts which make it useful to adhere to such conventions are indeed empirical. As we now use words, it is impossible, even in principle, for one person literally to share another's experiences; but it is not difficult to imagine circumstances in which we should find it convenient to adopt a different verbal usage.

Perhaps it is considerations of this kind that lead Russell to say, at the end of his book, that he believes it possible to make inferences "from the structure of language as to the structure of the world". He tells us indeed that the proof of this possibility "has been in a sense the goal of all our discussions". But if he intends this to be taken seriously, he seems to me to be setting too low a value on his book. For if he means only that the development of a language is partly conditioned by the nature of the facts which it is used to describe, his conclusion, though true, is not one that it would take a lengthy book to prove; while if he is referring to some more mysterious affinity between language and the 'world', it does not appear to have been established by anything that he has previously said.

A. J. Ayer.

THE MAKING OF THE 'MARITIMES'

The Cod Fisheries
The History of an International Economy. By Harold A. Innis. (The Relations of Canada and the United States: a Series of Studies prepared under the direction of the Carnegie Endowment for International Peace, Division of Economics and History.) Pp. xx+520. (New Haven, Conn.: Yale University Press; Toronto: The Ryerson Press; London: Oxford University Press, 1940.) 21*s*. 6*d*.

THIS is an important book (as well as a large one) about the great fisheries of the maritime provinces of North America, including New England, tracing their history from the days of Cabot's discovery of Newfoundland to the recent inglorious submission of that island to administration by British civil servants.

The book is one of a series designed to promote the mutual understanding of Canada and the United States. It is also introduced as a challenge to the imagination and insight of the reader, which it undoubtedly is, and Canadian and American students who master it may well have a fellow-feeling based on survival of the same ordeal, for it is uncommonly hard reading.

Yet the book is saved by its very pedestrianism. It is a long and tedious tale of petty greed and sectional interests, in which it is usually the reader who has to contribute the thought that these men were venturing their all, or their lives, on arduous fishing in comfortless places, and in far voyaging with the catch to West Indies and Mediterranean; but there is a fascination in the record of commercial facts which passes across the pages with the precision and inevitability of the tape-machine: "Colonial shipping grew in importance with colonial trade. In 1763 St. John's shipped fish totalling 56,365 quintals. Of this, vessels from Philadelphia carried 2,967 quintals"; etc.; or, from a footnote: "Planters increased from 346 men in 1736 to 690 in 1747, and to 1,250 in 1764; servants from 3,727", etc.

There is another and greater virtue in the book, in that it does attempt to make sense of all this, to show the historical trends that have resulted in the present state of affairs in the Maritimes. Despite the long record of apparently unimportant detail, the author does establish his right to draw sweeping and important conclusions. Having traced the failure of the chartered company system, then the dominance of the English West Country Merchant Adventurers, whose power was destroyed by the multitude of small settlers, and the rise of their commerce, essentially a maritime decentralized economy, he shows how this in its turn has fallen.

"The transition from dependence on a maritime economy to dependence on a continental economy has been slow, painful, and disastrous. The tremendous initiative which characterised commercialism based on the fishing industry could be measured in the collapse of West Country company control over trade and the fishery, in the history of Newfoundland and New England, the defeat of France and the breakdown of the colonial system, the disappearance of the Navigation Acts, and even the rise of responsible government and the establishment of Confederation. This is an initiative which cannot be suddenly replaced. The effects of the tragedy of the replacement of commercialism by capitalism call for a long period of expensive adjustment and restoration, and this cannot take place without policies which foster the revival of initiative under responsible governments."

Those are Prof. Innis's closing words. As English I found the passage difficult, but unless I am much mistaken it is history of the most useful kind—that understands the past in order to forgive the present, and prepare for the future.

MICHAEL GRAHAM.

ANIMALS AND PLANTS AT HOME

The Open Book of Wild Life
An Introduction to Nature Study. By Richard Morse. Pp. 240+48 plates. (London: Adam and Charles Black, Ltd., 1941.) 8*s*. 6*d*. net.

MR. MORSE's book is meant primarily for younger readers, but it is not likely that many adults will begin reading it without being caught by its irresistible charm—the charm of the wild life of the British countryside and the charm of the writer's style. The book is based on sound scientific principles, and compresses an enormous amount of knowledge in a comparatively small compass. In fact, everybody can learn something from what one can only describe as a delightful book. It is not a text-book. It comprises the

observation and thoughts of a true lover of Nature. There is no evidence of any attempt on the part of the author to teach natural history (much less biology) to his readers. He proves himself here to be a literary "Zoo-man" or "Romany", telling his readers, as David Seth-Smith writes in his foreword, "in simple language, what to look for, and how to make one's country walks much more interesting than they have ever been before".

Thus he tells his readers a great deal that they will not find in their more formal text-books, and, indeed, he tells much that the text-book does not even explain, which is all to the good. It will set an enthusiastic reader wondering, and, above all, verifying by practical observation.

Even so, though the author does not attempt to teach biology in the formal way, his own style of presentation brings out the main biological principles almost surreptitiously. For example, after a fascinating account of the behaviour of the adult and young cuckoo (where he introduces the concept of instinct) he finishes :

"As soon as any plant or animal begins to steal from others instead of working for itself, it begins to lose some of its organs or some of its powers. It begins, in other words, to degenerate. Now the cuckoo affords a striking illustration of the working of that law, for it is quite plainly a degenerate bird. It is, for example, very unsociable—just the opposite of the highly intelligent rooks. Then again, the mother cuckoo, as we have already seen, cares nothing at all for her children, and she is herself a terrible glutton. How amazingly different she is from the pair of little blue-tits who brought home two thousand grubs and caterpillars for their young ones in a single day—a task which meant at least sixteen hours of almost continuous labour !

Exactly how the cuckoos first came to start their life of indolence and plunder nobody knows, but it is quite evident that they are birds that are going downhill. Their eggs are peculiarly small ; their internal organs are always in an unhealthy condition ; and they are hated and despised by vast numbers of their hard-working fellow-birds."

Few other books of this standard would put it like that.

Mr. R. Morse, Mr. Eric J. Hosking, Miss C. von Wyss, Mr. W. S. Berridge, Mr. D. Ferguson and Mr. C. A. Hall are all well-known nature photographers, and there are nearly fifty of their photographic studies reproduced here, together with some others. The fifty beautiful line drawings are by such well-known nature artists as Miss Doris Roger, Miss C. von Wyss and Mr. Roland Green. Some of the sixteen colour plates are particularly attractive, especially Roland Green's "Ruler of a Kingdom" (robins at home) and V. R. Balfour-Browne's "Our Largest Wild Animal" (red deer).

If this book achieves the success that it so richly deserves, it will be more to the advantage of its young and adult readers than to the author, who is deserving of praise and congratulation for such a charming and valuable contribution to popular scientific literature.

FARMING AND NATIONAL LIFE

England and the Farmer

A Symposium by Viscount Lymington, Sir Albert Howard, C. Henry Warren, Adrian Bell, Rolf Gardiner, Dr. L. J. Picton and Prof. Sir George Stapledon. Collected and edited, with an Introduction, by H. J. Massingham. Pp. vi+154+81 plates. (London : B. T. Batsford, Ltd., 1941.) 10*s*. 6*d*. net.

IN this book Mr. Massingham has collected a series of essays by well-known agricultural writers mostly belonging to the same school of thought, and he thus gives them an opportunity of restating their views on farming in relation to national life in Britain. In the main, they support what he calls the "Rule of Return", that is, the rehabilitation of the small yeoman farmer, the return of all waste products to the land, the avoidance of imports and the elimination of 'big business' ; and it is recognized that this involves a "return to smaller units of social economic life and the splitting up of the swollen topheavy communities squeezed into huge towns".

The advantages of small-scale general farming on our own soil, it is claimed, are so overwhelming that one wonders why it has not prospered here. Lord Lymington criticizes our present methods and states that "subnormality in health and degenerative disease are the average in this country" and this can only be cured by a general return to the land. Sir Albert Howard's solution is a more widespread adoption of the Indore method of making compost, which is based on the wisdom of the East : "in the Orient a fertile soil always means healthy crops" ; we should, he says,

retrace our steps and discard the use of artificial fertilizers "which history will condemn as one of the greatest misfortunes which has befallen agriculture and mankind". Facing this page is a good photograph showing the application of artificial manures in preparation for wheat on what looks like a very well-run farm.

Mr. Warren recognizes that we must continue to import corn but must also continue to grow it, and he argues in favour of a subsidy for keeping land in good heart rather than for particular crops. Mr. Rolf Gardiner gives a spirited account of the self-contained estate, which is a better unit than the self-contained farm, being larger and more comprehensive; but he cites no example that he can commend although several landowners have actually tried this method. Sir George Stapledon makes some calculations showing what might be achieved if the grassland of Great Britain were fully improved. Mr. Adrian Bell claims that the small family farm maintains the highest standard of fertility, yet admits that the sons try to get away from it.

That brings us at once to the crux of the problem. You may argue as much as you like with a young countryman about the joys of a peasant's life (which you are obviously not leading yourself), of the delight of working in the field from morning until night, of walking behind the plough, of swinging the scythe, etc. He is not interested. His idea, if he stays on the land at all, is to drive a tractor and let *that* do the work, to have a short day and abundance of leisure. It is unfair to blame the system of education for this; the responsibility is with the motor-cycle and the motor-bus, that take the young countryman into the town and show him how the machine and the scientific appliance can shorten the day's labour and at the same time increase the day's output. This has been the direction in which our agriculture has moved, thanks to science and engineering, and it has given our farm workers a higher output, better remuneration and easier conditions of life and labour than any others in Europe.

But the picture has another side; the output per acre in Britain has been low. In a general way there is often an inverse relation between output per man and output per acre, but this is not essential; and the great problem confronting British agriculture now is to raise the output per acre while maintaining or increasing the output per man, and it should be possible to do this without going back to peasant conditions.

E. J. RUSSELL.

SUGAR REFINING

Technology for Sugar Refinery Workers
By Oliver Lyle. Pp. 401. (London: Chapman and Hall, Ltd., 1941.) 15s. net.

THIS book gives a comprehensive account of the manufacture of refined from raw sugar. The author apologizes for his frequent reference to the refinery at Plaistow Wharf, but the apology is unnecessary since the author's experience at that factory gives him the opportunity of tracing the development of the industry during many years.

Short chapters are devoted to chemistry and physics in so far as these subjects are related to sugar refining. Full descriptions are given of steam boilers, electrical plant, pumps, evaporators and vacuum pans used in the refinery and there are detailed accounts of the successive stages of refining—filtration, char treatment, evaporation, boiling to grain, etc.—and of the methods of systematic control of the factory efficiency. In the refining process as carried out at the Plaistow Refinery, the total loss of sugar during a recent six-months period was only 0·7 per cent, a figure which speaks volumes for the efficiency of modern refining especially in view of the fact that most of the sugar is turned out as refined sugar of 99·9 or 99·95 per cent purity. The technical part is followed by an account of the transactions involved in the buying of raw sugar and sale of the refined article.

Very few mistakes have been noted in the text and only two are serious enough to warrant mention. On p. 72 it is stated that of the two rays into which light is separated by Iceland spar, one is plane-polarized and the other is ordinary light; actually, of course, both rays are plane-polarized at right angles. On p. 106 it is stated, in effect, that coal differs from wood and vegetation only in having undergone compression!

The author makes a very justifiable protest against the claim that glucose is preferable to sucrose as a food; this claim, developed in the first instance by advertisment, has unfortunately been accepted by many medical men.

The book is well printed and the illustrations are numerous and excellent.

LEWIS EYNON.

Bainbridge and Menzies' Essentials of Physiology

Ninth edition, edited and revised by Prof. H. Hartridge. Pp. x+687. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1940.) 16*s*. net.

"BAINBRIDGE AND MENZIES" first appeared in the early days of the War of 1914–18. It rapidly made headway and now rightly holds place as one of the standard text-books for the teaching of physiology. This, the ninth, is the fourth edition for which the present editor has been responsible.

Although this new edition has not demanded the extensive changes in subject-matter apparent in the last, the introduction of a considerable amount of new material has still been necessary. Nevertheless Prof. Hartridge has retained the same limits of length and size, a task which must have entailed laborious detail in revision. He has, further, continued the same plain method of presentation in distribution of content, in paragraphing, in type of illustration and in make-up generally, laid down by the original authors.

The book suffers from the defects of its title; indeed it always has. For the limits of its mere length impose mechanical restrictions calling for careful selection in the compression of material and in the proportionate balance given the different chapters. This is, of course, a problem which all technical writers, and in particular, teachers, have to face. In the present instance the aim of keeping "Bainbridge and Menzies" within the imposed limits has been carried too far. Both the standing and purpose of the book would well justify an expansion sufficient to allow a better balance and freer discussion. Physiology to-day is a different thing from what it was in 1914; it is scarcely reasonable to expect a volume of the same size to contain the subject as completely.

The Anatomy of the Eye and Orbit

Including the Central Connections, Development, and Comparative Anatomy of the Visual Apparatus. By Eugene Wolff. Second edition. Pp. x+374. (London: H. K. Lewis and Co., Ltd., 1940.) 31*s*. 6*d*. net.

THIS book makes a bid for a unique position both in ophthalmology and anatomy; it is easy to understand why a second edition has so soon been called for.

The subject-matter apparent in the title is fully and generously covered, the bony orbit and the eyeball, the appendages and the musculature, the vessels and the visual pathway. Mr. Wolff adds to the value of his book by his chapters on development and comparative anatomy; the latter is indeed, if choice may be expressed, one of the most attractive in the book.

The text is clearly and concisely written, seeking always a simple statement of fact, a property too often lacking in technical books; the account, for example, of the development of the iris and of the knotty problems concerned with that of the vitreous could scarcely be bettered. The neurological descriptions may also be remarked on.

Many of the numerous illustrations are original and some are really admirable; the drawings by A. K. Maxwell from sections by the author of Verhoeff's membrane may be cited as an example.

References are full and complete, and the book is well indexed.

The Calculation and Design of Electrical Apparatus

By Dr. W. Wilson. Third edition, revised. Pp. xv+240. (London: Chapman and Hall, Ltd., 1941.) 10*s*. 6*d*. net.

NO author could have had better press notices of a book than has Dr. Wilson of the earlier editions of this one and, as a natural corollary, one might say that the book has deserved every word of them.

The new edition contains additional matter and is not simply a reprint of the previous one. The two chapters on heating and fusing and on the calculation of heavy conductors have received most attention in the revision, more complete data being given on the calculation of convection and radiation losses, temperature conversion factors, time-constants, short-time ratings and conductor emissivities. In the chapter on system short-circuits a method is now given of finding the asymmetric factor and the duration of the D.C. component of asymmetric waves.

So far as heavy conductors are concerned, additional charts are included for the estimation of skin and proximity factors for bars, rods and cables, and the sizes of rectangular single and laminated bus-bars can now be ascertained by rational calculation instead of by semi-empirical methods.

Other miscellaneous data and worked examples are provided, all of which increase the value of this very acceptable book. S. A. S.

General Biology

By Prof. James Watt Mavor. Revised Edition. Pp. xxx+897. (New York: The Macmillan Company, 1941.) 4 dollars.

THE absence of a really coherent course in biology for students of general degree standard in Great Britain is probably one of the reasons for the dearth of good British text-books as compared with a large number of different American texts of which the book now before us is one of the best examples. It can be strongly recommended for the keenest students of Higher School Certificate standard, but more so should it be brought to the notice of all teachers of biology, no matter of what standard.

The book was published in 1936 and was such a success that it was necessary to reprint it five times; but the present edition is a totally new one. The pages have been increased in size and their number has been advanced by about one-sixth, with a corresponding increase in number of illustrations. The latter increase is due largely to the incorporation of a number of excellent photographs.

The author also presents a suggested schedule for a thirty-week course of practical laboratory work for the use of teachers, who are often sadly in need of guidance and who usually lack enough initiative to depart from the deadly 'type' system imposed by the prevailing examination system.

Introduction to Algebraic Theories

By A. Adrian Albert. Pp. viii+137. (Chicago: University of Chicago Press; Cambridge: At the University Press, 1941.) 10*s*. 6*d*. net.

PROF. A. ADRIAN ALBERT is well known for his outstanding research in algebra and, in particular, the structure of non-commutative algebras. His "Modern Higher Algebra", published in 1938, presented the first English text of modern algebraic theories on a purely abstract basis. In the meantime, he has been concerned with the obviously serious gap existing in the mode of thought between the intuitive treatment of the theory of equations and the essentially rigorous and abstract methods of the "Modern Higher Algebra". In spite of the attempt to bridge the gulf by the publication of several more abstract presentations of the theory of equations, Prof. Albert felt that the only satisfactory course was to provide a new introduction to algebraic theories, and the present volume is the result.

The text begins with polynomials and then passes to a full discussion of the theory of matrices with simple modern proofs. The six chapters are written with great clarity and are well illustrated by many new types of numerical exercises. The last chapter—on fundamental concepts—is a noteworthy and illuminating introduction to the study of abstract algebra. Any student who has a good knowledge of the usual theory of equations and of determinants will be able to follow the course without difficulty. To those interested in the application of the theory of matrices to statistics, economics and psychology, this book should also be very useful.

Embryology of Insects and Myriapods

The Developmental History of Insects, Centipedes and Millepedes from Egg Deposition to Hatching. By Prof. Oskar A. Johannsen and Ferdinand H. Butt. (McGraw-Hill Publications in the Zoological Sciences.) Pp. xi+462. (New York and London: McGraw-Hill Book Co. Inc., 1941.) 35*s*.

WITH the growth and rise of the modern subject of experimental embryology, renewed interest has asserted itself in regard to the 'normal' developmental phases of animals. The resulting demand is likely to be for more exact studies of the development of individual organs and parts. In this connexion the re-investigation of their intimate origins, cell by cell, seems likely to be called for. In so far as insects are concerned, the experimental aspects of their development have not, as yet, progressed very far, and at this stage a stock-taking of the position as regards the general embryology of these animals is opportune. This has been provided for in the new book by Messrs. Johannsen and Butt, who have restated the modern position of the subject in a clear and readily understandable style. Both authors have published original researches in embryology which qualify them for this task. Their work is one of judicious compilation and the unbiased assessment of conflicting views: in both these respects it has been ably accomplished.

The book is divided into two parts, of which Part I is a general comparative account of the development of insects and myriapods. This part also includes a useful chapter on experimental embryology, based on a review of the subject by Richards and Miller, published in 1937. Short chapters on polyembryony and parthenogenesis and on micro-organisms in the egg are also included. In Part II the embryology of leading types of the different orders is described. Thus, for the Orthoptera the work of Roonwal on Locusta is freely drawn upon both for figures and textual matter. For the Coleoptera the junior author's account of the weevil Brachyrhinus forms the basis, and for Scolopendra, Heymon's well-known memoir provides the necessary data. These several accounts contain very adequate illustrations and at the end of the book there is a bibliography of more than 700 references.

The letterpress is well up to date, and it is pleasing to see so much attention paid to the findings of recent research. By way of criticism certain features require mention. The account of the Myriopoda is disappointing on the whole, especially with reference to the Diplopoda. Also, the authors' attention is invited to their use of unfamiliar group names such as Oligoentomata, Aptilota and Oligonephridia, which are left undefined and are likely to confuse the student. These are minor blemishes in a thoroughly sound text-book. A. D. IMMS.

The Tutorial Algebra

By Dr. William Briggs and Prof. G. H. Bryan. Fifth edition, revised and re-written by Dr. George Walker. Vol. 1: Intermediate Course. Pp. xv+457. (London: University Tutorial Press, Ltd., 1940.) 7*s*. 6*d*.

THIS is the fifth edition of a well-known book written originally as a text-book for students taking the London intermediate and degree examinations. In consequence of the many changes which have taken place in the mathematical syllabuses prescribed for these examinations, as well as the improvement in teaching methods, it became necessary to revise completely and extend the scope of this work. It has thus been expanded into two volumes of which the book under notice is volume 1.

This covers all the algebra required for the London intermediate examinations except that for economics. It begins with the theory of indices and elementary ideas of complex numbers. The usual course is then followed up to the binomial theorem, interest and annuities. The sections devoted to equations are especially noteworthy and comprehensive. Particular stress is rightly laid on the functional notation and attention is early directed to the properties of partial fractions. Exercises in abundance, with answers, are supplied for the student's practice, and many of these have been taken from recent examination papers. Special emphasis has been laid on the diversity of types of examples, and a large number have been fully worked in illustration of the text.

The book is very attractively bound and the printing is very clear. It should prove very useful to students of algebra whether reading for the relevant examinations or not.

DEVELOPMENT OF HEAVIER-THAN-AIR CRAFT

By The Right Hon. J. T. C. Moore-Brabazon, P.C., M.P.
Minister of Aircraft Production

GLIDING flight, so patent to all watchers of Nature, seems to have been neglected through all the ages. There was little reason why efficient gliders could not have been constructed with the materials at the hand of many preceding generations, and had this been pursued with vigour the high-efficiency glider might well have come into use and the motive power required deduced therefrom to get sustained flight. The early pioneers of gliding flight never reached a glide of one in ten, but Lilienthal, Chanute and others were getting near that angle when the Wright brothers with their flexible biplane, controlled fore and aft aerodynamically instead of by transference of weight, showed a real advance in stability and the possibility of the introduction of an engine.

December 17, 1903, marks indeed a very great day in human progress and no credit is too high to pay the two Wright brothers for the tremendous concentration that they must have devoted to the construction of this machine, for not only did they construct the actual machine but also in fact, built an engine—no mean feat—which after gearing down by chains to two large-sized propellers, gave the necessary propulsive power to sustain flight. It is interesting to note that in the Wrights' patent their claim was for lateral stability. By gliding experiments they had found that putting extra warping on the depressed wing did not restore the aeroplane or glider to horizontal unless it was accompanied by rudder to force it to maintain its speed. The control for this was complicated, the rudder and side control being put on one lever, which was soon, however, found inconvenient. What is remarkable is the hiatus between the original experiments at Kitty Hawk and the demonstration of sustained flight which the Wright brothers gave in the United States and in Europe as late as 1908—five years. This latter machine, judged by the original which is now in the Science Museum, had become more robust, the under-carriage stronger and the engine more powerful, but generally the same scheme was adopted with the tiresome launching by virtue of reposing the machine upon—so to speak—a type of sleeper on roller skates which ran down a single rail pointed in the direction from which the wind was coming. Acceleration down this rail was accentuated by a weight hoisted in a pylon falling, it being attached round the end of the rail through a pulley and back to the machine. Acceleration to about 45 m.p.h. was obtained in 90 ft. by virtue of the kinetic energy of the weight and push of the propellers.

Analogous experiments had been proceeding in Europe. Santos Dumont had obtained a flight of about 100 metres with a vast dihedral biplane with no lateral control, of a very big box type with control in pitch for'ard. This flight took place in 1906. The propelling power was a very remarkable engine built by Levavasseur, a genius in design. The propeller was coupled to the engine shaft, but the engine was very remarkable for those days. It was an eight-cylinder V type. It had copper-deposited water jackets and fuel injection—an engine in fact twenty years ahead of its time. It was with this engine, however, that Farman in Paris with a biplane built by Voisin, again with no side control but with a stabilizing tail and single horizontal rudder in front, won the Archdeacon prize for a sustained flight of a kilometre in 1908. I flew several of this type; they were unstable in pitch and laterally uncontrolled.

The only outstanding aeroplane in those days from an aerodynamic point of view was the Antoinette, which was flown by Latham. Here again Levavasseur designed not only the engine but also the aeroplane, introducing steam cooling, a thing we have not yet reached in modern practice. This machine in its day was, I think, the most graceful, being a centrally winged monoplane, and it was a pity that it did not go down in history as the first machine to cross the Channel, as twice Latham failed by a matter of a few hundred yards.

There was a general attack upon flight in Europe by a succession of more and more powerful engines on singularly inefficient aircraft; exception might perhaps be made to the Bleriot, a light type of monoplane with warping wings, open fuselage and tractor screw. This historical craft that crossed the Channel was driven by an Anzani three-cylinder engine, but never again did this engine or one of similar type run for such a long period as when crossing the Channel, the reason being that it was kept cool and avoided overheating by virtue of a rain-storm which cooled it!

The next important contribution along the lines of excessive power rather than aerodynamic efficiency was the introduction of the radial engine of a rotating type, not the non-rotating radial as we see to-day. This was the famous Gnome engine. It had seven cylinders, exhaust valve on the top, and gave roughly about 40 h.p.

at 1,100 revs. per min. At first the amount of lubricating oil that was wasted by escaping centrifugally through the exhaust valve made the consumption of lubricating oil almost equal to that of the petrol. Somebody cleverly suggested the use of castor oil, which has the peculiarity of getting stickier the hotter it gets, and from that moment there existed an engine which was certainly comparatively reliable and successful.

Many remarkable flights were made with this engine, including the first London to Manchester by Paulhan and the glorious failure by Graham-White in the same competition. This was a great engine which contributed very much towards flight in Europe. Speeds, of course, had increased by now—and I am referring to 1910–11—from about 45 m.p.h. to 60 and 70 m.p.h. and the general trend was towards the monoplane type of construction in order to avoid parasitic drag. Seaplanes had come in by now and the Schneider Cup —the blue ribbon of seaplane racing—was won by that type of machine. The monoplane fetish was, however, completely upset by Tommy Sopwith's attack on the Schneider Cup, when he appeared with a biplane (1914) and had at least thirty-five miles up his sleeve. Again we were back to biplanes.

No great advance from the point of view of use—apart from exhibition—had been made until the outbreak of the War of 1914–18 when there was a tremendous concentration, regardless of economy or anything else except the war outlook, on aircraft in general. Some very remarkable machines and engines were constructed under pressure during that War. Machines jumped in horse-power from 50 to nearly 500, and they were exceeding 120 m.p.h. towards the end with regularity. The outstanding machines of the War were the Bristol Fighter, a biplane fighter—reconnaissance machine as we would call it now, two-seater, with engine, a Rolls, rather high up between the two planes; the Handley Page big bomber; and among fighters, the S.E.5, Sopwith Pup and the Camel. It is interesting to note that the 'pusher' type of machine was still favoured by some. The general trend of engine design on the British side at any rate was the multi-cylindered type, whilst the Germans concentrated on big six-cylinder units in line. The mushroom growth of aviation forced upon the world by war caused a very great reaction afterwards. Great Britain threw away her predominance in the air, and there was not very much imagination shown towards the possibility of joining the Empire closer together in time by virtue of flight.

Holt Thomas certainly had vision but no machines. He endeavoured to run a service to Paris and elsewhere on the Continent with old war machines, but the enterprise failed. But the idea that civil aviation had a future was born never to be killed. Generally it was realized, however, that civil aviation could not, in the words of the present Prime Minister speaking at that time "fly by itself", and subsidies throughout the world were started in order to foster civil aviation. But most nations spoke with their tongue in their cheek because fostering civil aviation meant, in fact, fostering an aviation industry built to make war machines. In fact some countries deliberately used war machines for civil purposes in order to find a use for them. Germany developed a very intensive internal non-economical commercial service in that they were not allowed war machines, but they were potential war machines. Great Britain started building two-engined heavy machines, but of vast surface with light wing loading—notably the Heracles built by Handley Page, slow, but a reliable money-making attempt at civil aviation.

However much various governments strove to get advanced with the ideal bomber, the real advance in aviation and especially in civil aviation came from the intense local competition which was being waged in the United States—a country ideally situated for long-distance air transport—among the various companies operating there in conjunction with manufacturing units.

Just as the Mercedes car suddenly emerged upon the motoring world five years ahead of anything else, so in aviation the Douglas machine marks an epoch in development. Here for the first time we had a machine completely clear of extraneous speed-reducing impediments. It was a skin-stressed machine, twin engine, tractor, of beautiful lines and of great comfort, and had three outstanding aerodynamic advantages: first of all the variable pitch propeller, which enabled it to get off with little run by virtue of low gearing the propellers and after attaining height increasing the pitch. It had a retractable under-carriage which in the realms of 200 m.p.h. meant a very great saving in drag and increased the speed for power. It had flaps which enabled the machine when they were depressed to take up a very coarse gliding angle, and allowed a machine so beautifully faired to come to rest in quite a small field, without running on. This machine was built ostensibly to serve the world, but is to-day the prototype for every long-range bomber. It is indeed a tragedy that a machine designed entirely for civil purposes should turn out in fact to be the ideal long-range bomber.

The radial engine and the liquid-cooled still continued to fight their battle for supremacy. The horse-power now is in the range of 2,000 and weights round about a pound per horse-power. Liquid coolers have the advantage of small frontal area; radials are simpler by virtue of air cooling. Height has now become a necessary part of engine

design, and here we find that it is not a function of power alone but of maintaining power at height by boost. Various boosts have been introduced on engines varying between the two-stage, two-speed blower, to the exhaust-driven turbine type.

I suggest that the future economical cruising stratum will be in the neighbourhood of 35,000 ft. If that is to be the right level then passengers cannot be asked to put up with the barometer at less than 6 in., so that pressurized cabins suitably heated and pressed will become the standard order of the commercial machine.

Long-range bombers have drifted into the four-engined type of great reliability with speeds up to 300 m.p.h., but they are voracious petrol eaters. Single-seater fighters with engines of 2,000 horse-power with wings not too heavily loaded, so that manœuvrability is not impaired, exceed the 400 m.p.h. mark. That is where we are to-day.

How all this is to be exploited for the benefit of inter-communication afterwards is difficult at present to say, and it is not clear how loads can in fact yet pay. We have perhaps come to the definite end of a type again, and it is not certain whether the tractor will eventually survive against the pusher, or whether present power units, with their big disk area propellers, are the end of the story. Aeronautics is now a science and development will not stop. There are great possibilities looming ahead, revolutionary in character ; but the present situation may be prolonged by a great increase in wing loading with assisted take off.

Here is a brief résumé of the results of those first experiments by the Wrights. (Mr. Orville Wright celebrated his seventieth birthday on August 19. See NATURE of August 16, p. 191.) It is indeed the duty of man to see that what the Wrights first introduced—one of the greatest inventions and contributions to mechanical science—is eventually used for the benefit of the world and not for the destruction of civilization. We cannot blame the Wright brothers for the prostitution of their invention that has taken place. Those of us who knew the two brothers will always cherish affection for them and the memory of two remarkably quiet, charming people. It will be for succeeding generations to prove that they introduced into the world, not a curse, but a means of transport which will eventually bind nations together on a basis of mutual understanding and goodwill.

CROP DAMAGE BY AIR ATTACK

By SIR JOHN RUSSELL, F.R.S.
ROTHAMSTED EXPERIMENTAL STATION

TWO possibilities of damage to crops by enemy action are now so near that warnings have been issued along with instructions showing what is to be done should the necessity for action arise. The Ministries of Home Security and of Agriculture have sent out to farmers three leaflets giving simple but precise methods for coping with attempts to destroy our crops either by fire or by poison gas.

In regard to fire, the problem is an old one in Australia and in Canada, so that a certain amount of experience is already available. In both countries the prairie or bush regions are liable to become very dry during periods of drought, and a spark or even a cigarette end may start a conflagration that races over miles of country, causing havoc wherever it goes. I shall never forget the Australian bush fires in the summer of 1938–39 (December and January) ; they were impressive beyond words, and one marvelled at the skill and courage of the Australians in facing up to what seemed irresistible devastation, gradually limiting and finally subduing it. In Great Britain experience is far more limited, and except for occasional fires started by picnickers or campers in young forestry plantations, the only fires ever seen in British fields are those caused by sparks from railway engines. But, small as it is, this experience is invaluable at the present time, and has clearly been drawn upon in the preparation of these pamphlets.

The reason so few field or forest fires are seen in Great Britain is, of course, the unsuitability of the climate. Occasionally, it is true, we get a summer where crops and grass dry up and look as if they would burn easily. 1940 was an example, and it is fortunate for us that the Germans made no large-scale attacks then. 1941 has been much wetter, and nothing could have fired the crops this summer. In spite of this, however, the Ministries are taking no risks, and are issuing instructions should the case arise.

Greenleaf crops are obviously exempt from risk, and the only danger might come to cereals. Oats are usually cut before they are dead ripe, and they normally still contain so much sap as to be non-combustible ; no danger arises from railway-engine sparks, and it may be assumed that incendiary

leaves or bombs would be harmless. Wheat is left longer and dries out more: it does not usually, however, become dry enough to burn easily, and railway-engine sparks rarely set a wheat field on fire. Barley, however, is generally left until it is dead ripe, and becomes drier than any other of the cereals, hence it is most likely to catch fire. Even so, barley fires are not very common, considering the number of barley fields in the country, and the total loss of standing corn is not great. As barley fields are scattered in among oat, root and grass fields, the danger of spreading, even if a fire should start, is only small.

The most serious risk is on the stubbles, if very dry weather should set in after the harvest. The short residual straw easily dries sufficiently to become inflammable, and if a fire starts it creeps over the field. There is no harm in that, so long as the fire keeps to the stubble; even some good may result if the heat is sufficient to kill insects and their eggs, and to destroy fungi and weed seeds; also the heating of the soil liberates plant food. But if sheaves of corn are still standing out, or if a stack of corn or of hay has been built up in the field, then there is danger that it may be set on fire.

Fortunately, Australian and Canadian experience shows how to give protection: the stubble should be ploughed up as speedily as possible, or if that be impracticable, then strips must be ploughed so as to divide the field into compartments; if a fire starts in one of them it can go no farther. Stacks must be well isolated from each other and from the stubble; they are best put in grass or root fields, but if they must be in a cereal field they should be surrounded by a belt of ploughed land.

Hedges also are liable to catch fire, especially if they contain much dry material at the bottom, as not infrequently happens. The precaution here is to keep the hedge well cut back and well cleaned.

In view of the fact that most of our grain is grown in the dry parts of England, the amount of water available for putting out a fire may not be great. Methods are indicated in the leaflets for organizing water supplies, and making such arrangements as are possible beforehand for facilitating action when the fire comes. Beating is effective, and although many parts of the country-side are familiar enough with the simple form of this operation that suffices for dealing with gorse and heather fires, a serious field fire would need more elaborate precautions, and these are duly described.

This fire danger has attracted the attention of a number of the farmers' organizations. The Hampshire Branch of the National Farmers' Union has issued recommendations which include such important details as the cutting and ploughing up of fire breaks through standing crops across the direction of the prevailing wind, but emphasizes the need for organizing groups of fire watchers and helpers, since the first minutes are always the most important.

The danger from gas is more oppressive because it lies right outside the countryman's experience, and every untested danger seems terrifying until it has actually come. It might not come at all, and if it does, it might prove relatively harmless. Certainly, the bombs that caused so much fear in the country-side before they arrived were treated with scant respect once it was seen how little damage they do in a field: a hole that is quickly filled in, or a fence that is soon mended, and all signs are removed. Many farm-workers have spoken contemptuously of the bombs: "They didn't even kill a rabbit" was a common phrase, and there was great relief at finding that the much-vaunted terror had so little substance. There is, of course, a world of difference between an open field and a crowded city.

It is possible that gas bombs in the fields would be equally innocuous, but the Ministry has set out instructions as to what should be done if they come. As the instructions cannot cover every possible case, the first and chief one is to get in touch promptly with the gas identification officer of the local authority.

Only persistent gases are considered likely to do serious harm, and of these the blister gases are the most important, especially mustard gas; but it is stated that still further caution would be needed against lewisite, on account of the risk of arsenic poisoning. Two modes of distribution are dealt with: by bombs and by spraying; bombs cause intensive contamination over a small area, and spraying a less intense contamination over a larger area. The crops become discoloured or scorched in appearance, and some of the liquid may remain either on the plant or on the soil; mustard gas has a faint, rather onion-like smell, while lewisite sometimes, but not always, has a smell of geraniums. The instructions to the farmer are quite simple: he must keep human beings and animals out of the affected areas, and get in touch with the local A.R.P. authorities, who will presumably have access to experts able to give fuller advice. Visibly damaged crops should not be fed to animals, though if grain crops survive and continue to grow, the expert might advise that they could be used as seed.

Stored crops usually present less difficulty. The usual protective agents, clamps, thatch, barns, and tarpaulins are said to be adequate against blister gas, and nothing more than prolonged airing is needed to overcome the trouble. Concrete silos

give complete protection, so long as the top is closed, but wire and paper silos may not always prove adequate, and a certain amount of dismantling and cutting out may have to be done. Stack or clamp silos afford no protection, and any part that has been splashed or sprayed must be removed and destroyed. Running water is safe, and need cause no anxiety, but water in shallow ponds or storage tanks, if contaminated with blister gas, may remain dangerous for long periods.

Naturally, one hopes that these particular dangers may never arise, but it is comforting to realize that if they should the Ministries of Agriculture and Home Security are alive to the possibilities, and that farmers have been forewarned and advised as to what steps they should take.

DRUG PLANTS NATIVE TO GREAT BRITAIN

By Dr. W. O. James

Botany Department, University of Oxford

APART from herbalist simples, there are some half-dozen or so plants of Europe and the British Isles which yield drugs of first-class medical importance. The annual consumption of Great Britain runs into hundreds of tons of crude dried material, almost the whole of which normally comes from the Continent, particularly from Belgium, Germany, the U.S.S.R. and the Balkans. Consumption is not limited to the requirements of the people of Great Britain. A re-export trade of refined drugs exists on a considerable scale and, since this largely goes to the western hemisphere, and is economical in its demands on cargo space, there is point in trying to keep it alive at the present time.

First, however, must come home needs. The Ministry of Health has issued several pronouncements stressing the importance and urgency of the question of supply and, through its Vegetable Drugs Committee, has reviewed the situation and made certain cautious recommendations.

Serious shortage already exists of some of the drugs in question, a situation which had its parallel in the War of 1914–18. The steps taken then were only partially successful, but should afford some useful background of experience now, though it is too early yet to say whether the implied lessons have been learnt.

The steps open to us include collection of wild plants and increased cultivation. Each is very narrowly restricted both by botanical and economic causes and will require skilful and determined handling if anything useful is to be achieved. The Ministry of Health has ruled that war-time production must remain on a commercial basis. Strictly speaking, this is impossible. It is true that the produce is being handled through the usual trade channels, but collection depends upon volunteers who can receive nothing commensurate with any normal valuation of their time and labour. This end of the effort is essentially a gift to the country—a commendable if indirect war-service—and should be recognized as such. It is being undertaken by women's institutes, women's voluntary services, boy scouts, girl guides and some schools.

Government assistance has not been lacking. The Ministry of Health has sought to give a lead, and has provided machinery for co-ordination and advice. In hard cash, grants have been given to certain famous and well-established firms to enable them to extend their drying-plant and, on a smaller scale, to the Oxford Medicinal Plants Scheme, which has been called into existence to make selections from the native wild plants, combining trials with a limited scale of present production.

It has been officially recommended by the Ministry of Health and the Medical Research Council that effort be concentrated on *belladonna*, colchicum, *foxglove*, male fern, *henbane*, sphagnum, *stramonium*, dandelion-root and valerian, with special emphasis on the four italicized. This recommendation does not seem to have received all the attention it deserves. Besides these plants of well-established therapeutic value, the flora of Great Britain contains many more which are normal articles of the drug trade, but the value of which no responsible medical man would put in the same category. Bluntly speaking, nobody is going to die prematurely or suffer great pain for lack of them, as many might suffer or die for lack of belladonna or foxglove. By no effort of the will can the harvesting of such inessentials be made to appear a significant contribution to the war effort. Nevertheless, judging from the inquiries and literature I have received, there seems to be a real danger of anxious and willing help

being dissipated upon them. Nor does it appear an adequate argument that there are districts where none of the important drug plants are to be found. In such places, which are, of course, numerous, effort would be better directed to something else; the much-besought women's institute member might better be left at her preserving-centre and her husband on his allotment.

Cultivation is limited to the 'big four', with some valerian. It has its own special difficulties and seed is not easy to come by. Moreover, the market could very easily become over-supplied if cultivation were begun by numerous growers on a large scale. It is clearly undesirable to stimulate a demand for such plants artificially, and for these reasons growing by amateurs and farmers, other than the already established specialists, has not been encouraged. The latter, however, have somewhat expanded their normal acreage.

The appeal for public assistance is concerned with collection. Within my own experience landowners have usually proved helpful and co-operative. A few wish to sell, especially where belladonna is concerned, and there have been very rare refusals of help or permission to collect.

The real crux, however, lies in the question of drying. Fresh herb as collected cannot be transported over any considerable distance both on account of prohibitive cost and of damage by bruising the leaves. Ten or fifteen miles is an extreme range and the latter figure is probably beyond it. It follows that the really worth-while effort is to get drying-sheds established in the centre of a zone thickly populated by the plant required. This puts foxglove into a class by itself. Valerian root may be collected in some swampy districts; henbane is rare in quantities large enough for commercial gathering though I have received reports of "fields full" here and there. We are able to collect a small amount of belladonna in Oxfordshire and the adjacent counties, but other resources are slender. Colchicum and male fern are locally abundant and worthy of serious attention in the west. Stramonium is only an occasional escape and inhabitant of waste-tips. The collection of dandelion root is a formidable undertaking and its use for the relief of dyspepsia, valuable though it is, is not to be compared with the irreplaceable role of digitalis as a cardiac stimulant. Foxglove, moreover, exists in abundance over wide areas which are still largely untapped. Initial results obtained by the Oxford Medicinal Plants Scheme, with the co-operation of the Botany Department at Bangor, suggest that the foxglove on the Welsh hills has an unusually high digitalis potency. An exceptional effort towards its gathering would seem to be indicated.

Everyone is agreed that drying-plant must be of a makeshift kind. There is no guarantee of a certain market for these products after the War; in fact they are more than likely to be displaced again by cheap imports from the Continent. Capital sunk in permanent drying-sheds would be sunk indeed. The temporary use of hop-kilns has been suggested; but very considerable additions of shelf-area are needed since drug plants are wetter and need much thinner spreading than hops. Consultation with a firm near Oxford made it clear that the attempt was likely to involve serious financial loss. Forced-air systems with their relatively high running costs appear to be out of the question. Occasionally, institutions are willing to allow the use of large airing-rooms with central heating. Since there is then no further outlay for fuel or shelving, this plan works to admiration. The only method of general application is that of the handyman who can knock up shelves of wood and netting in some available outhouse. When allowance is made for putting in the essential stove, the most modest attempt involves an expenditure of ten or fifteen pounds. Ten pounds is the market value of about 2 cwt. of dried foxglove leaf, or getting on for a ton of leaf as gathered—far more than such a shed could handle in a single season, and this is making no allowance for coke and other costs of operation. There is also implied a great deal of active gathering by a considerable number of women or supervised children in the field and a great deal of uncomfortably hot and tiring work spreading and turning the leaf in the driers.

Each drying-centre, small though it may be, needs the constant supervision of a man or woman of untiring and persuasive nature to keep it actively in operation. A modicum of expert knowledge is also needed, and there is much greater scope and need for the help of botanists on the spot than has yet been realized. Botanists are often exercised at the present time as to how they can turn their special training to the public good. Those of a practical turn could find something valuable and patriotically useful to do in building up and running such drying-centres. It need not be at all a routine job. Very little seems to be known about the best methods of drying, a purely empirical judgment of colour being a common basis of values. There is need for the collection of numerous data both for direct technical and more academic purposes. This amounts to a good deal more than spare-time work and can probably only be achieved as a recognized activity for a botany department. In my view, the help of many more such institutions and their personnel is essential if this war-time emergency work is to be carried out with full success.

PHYTIC ACID AND THE PREPARATION OF FOOD

By E. M. WIDDOWSON,
DEPARTMENT OF MEDICINE, UNIVERSITY OF CAMBRIDGE

NOW that something definite is known about phytic acid metabolism and about the extent to which this compound interferes with the absorption of calcium, the quantities in our daily food have become almost as important a nutritional counter as the amounts of calcium. In fact, following Harrison and Mellanby's work on dogs[1], and the experiments on men and women which have been carried out in this Department[2], it has become clear that the phytic acid/calcium ratio determines whether a diet will promote the absorption of calcium or facilitate the production of rickets. Foods have been analysed for calcium and for phytic acid, but there is another aspect of the matter which has not yet received the attention it deserves. It is known that the rat possesses a digestive enzyme which will hydrolyse phytic acid[3]. It is thought that other animals have not; and consequently it is generally assumed in human nutrition that the phytic acid in wheat and other natural foodstuffs can be broken down only by the bacteria in the intestine. There is, however, a phytase in wheat, and the purpose of this note is to show that this enzyme is active in commercial flours, and that it may destroy phytic acid during the accepted cooking processes.

Phytic acid in wheat is located chiefly in the bran, and consequently the more bran included with the flour, the greater the amount of phytic acid in it. Representative figures may be taken to be follows:

		Phytic acid mgm./100 gm.
White flour	70% extraction . .	51
National Wheatmeal	85% extraction . .	127
Wheatmeal	92% extraction . .	214

The table opposite shows the destruction of phytic acid which has been found to follow the conversion of these raw materials into food. It will be seen that baking with yeast led to considerable hydrolysis, and the more refined the flour, the greater the percentage destruction. In fact, the phytic acid in white flour was very largely removed by this process. 'National' bread also contained much less than the flour from which it was made. 92 per cent flour not only contained most phytic acid, but also the percentage destruction on baking was the least.

There was very much less destruction when baking powder replaced the yeast, and there were probably two reasons for this. First, when the yeast dough was set to rise, it afforded the enzyme an opportunity to act upon its substrate before it was itself inactivated by the rise of temperature in the oven. In baking with sodium bicarbonate and cream of tartar the doughs were put into a hot oven as soon as they were mixed and the temperature was rapidly raised to a point at which the enzyme was destroyed. Secondly, the optimum pH of wheat phytase is in the region of 5·5[4]. The enzyme is never given a chance to act at this reaction in the usual cooking processes, but the hydrogen ion concentration of a yeast dough is much more favourable to the activity of the phytase than that of a baking powder dough. As might have been expected from the results with bread, there was some destruction of phytic acid during the preparation of a steamed pudding. This was cooked in the usual way in a pudding basin, and was of a size suitable for five or six persons, so that the temperature of its centre probably rose quite slowly. There was no destruction of phytic acid in the baking of wholemeal pastry. This was made with a dry dough and heated very rapidly.

DESTRUCTION OF PHYTIC ACID ON COOKING

Nature of flour	*Cooked product*	*% destruction of phytic acid*
White (70%)	Yeast bread . .	85
National Wheatmeal (85%)	. . . . .	69
Wheatmeal (92%)	. . . . .	31
,, ,,	Baking-powder bread.	5
,, ,,	Steamed pudding .	16
,, ,,	Pastry	0
White (70%) with added sodium phytate	Baking-powder bread	15
,, ,,	Steamed pudding .	60
,, ,,	Pastry . . .	15

The table also shows the destruction of organic phosphorus which took place when enough sodium phytate was added to white flour to make its concentration equal to that in 92 per cent flour. More phytic acid was destroyed in baking and cooking with this product than with 92 per cent flour. This may have been because sodium phytate is more soluble than the phytates naturally occurring in the wheat, but in any event there was evidently an active phytase in the 70 per cent flour. Hence, either the enzyme is naturally more dispersed than its substrate through the endosperm, or it becomes separated from its substrate by the milling processes.

The cheapest and most effective way of frustrating the noxious action of phytic acid is unquestionably to add calcium to flour, but something can evidently be done by cooking in a suitable manner. It is hoped that these observations—in the present emergency or later—may find some application to the service of man.

Miss B. Alington prepared most of these foods. The expenses were covered by a grant from the Medical Research Council, and the author is in the whole-time service of the Council.

A CLASSIFICATION OF THE EOLITHIC INDUSTRIES OF ENGLAND

By J. Reid Moir, F.R.S.

In view of the considerable number of discoveries made in England of eolithic implements of various kinds, it seems desirable to attempt a classification of these artefacts, as a first step towards that which has been made of the later palæolithic industries. There is no doubt that the original classification of these implements was of great value as enabling us to visualize the main stages of palæolithic man's existence, and the great length of time absorbed during the ebb and flow of his material advancement. Though the late Prof. Rutot of Brussels published, many years ago, a classification of the eolithic industries found in Belgium and France, no attempt has, hitherto, been made to classify the English eoliths—the study of which remains in the unsatisfactory state of the palæolithic artefacts in pre-classification days.

It is necessary, however, to point out that the classification of the English eoliths must differ in an important manner from that which has been formulated for the palæolithic industries. In the case of the latter many actual 'floors', or sites of occupation, have been found resting upon, and covered by well-known deposits of which the geological age has been ascertained. Though very ancient, the palæolithic races lived near enough to our own time to make it possible for some of the beds in which certain of the land surfaces on which they lived, were embedded, to survive the intense, destructive geological agencies which have operated since these beds were accumulated. Thus it has been found possible to fix, with considerable accuracy, the geological age of certain palæolithic 'floors' in England. But, in the case of the eoliths, the passage of time since they were made has been so extended that the deposits in which they were originally embedded have, in England, long since been destroyed, and the eolithic artefacts are now found only in beds composed of the wreckage of these older deposits.

The Suffolk Bone Bed, beneath the Red Crag, is a typical example of such a *remanié* accumulation, and contains, in addition to the bones and teeth of land mammals of late Miocene and Pliocene age, together with certain pieces of fossil bone artificially shaped, no less than five groups of flint implements which, by their differing patinations, and re-worked examples, can be recognized as of different ages[1]. As these remote relics of man are found, almost exclusively, as derivatives in the Suffolk Bone Bed, of Upper Pliocene age, it follows that their makers must have lived in some at present unspecified period, or periods, prior to that in which this bed was accumulated. There would appear to be six eolithic stages represented in England—though more may eventually come to light—and these are as follows :

(1) *Kentian.*—The Kentian specimens were first found by Benjamin Harrison in and upon the high plateau gravel of Kent. They are made, chiefly, from naturally produced pieces of flint of tabular form, which have been modified by steep flaking along their edges, causing them to assume the shapes of points, borers and scrapers of more than one type. For many years after their discovery the age of the Kentian eoliths, though regarded as, in all probability, very great, remained unknown, but it is now apparent that another series of eoliths, the Cantalian, found at Aurillac, Cantal, in central France, resembles the Kentian artefacts so closely that it is reasonable to suppose they are of the same age[2]. The geological deposit, a gravel, in which the Cantalian eoliths occur, is fortunately known, and referable to the Upper Miocene period. The following five groups of eoliths were found in the Suffolk Bone Bed beneath the Red Crag.

(2) *Bramfordian.* The Bramfordian specimens were discovered, most frequently, in Coe's pits, Bramford, near Ipswich. The colour of the majority of the flints is a peculiar archaic-looking, washed out yellow, while they exhibit signs of

much rolling by water action and heavy striation. The Kentian tradition is very clearly marked in these specimens, which, however, show an advance in technique as they are often made from primitive flake implements exhibiting steep edge-flaking. Rostro-carinates are present in this group.

(3) *Boltonian.* The Boltonian specimens occurred most freely in Bolton and Co.'s brick-field, Ipswich. The prevailing colour of the flints is a rich chestnut brown carrying a well-marked gloss, and they show considerably less signs of rolling and striation than the Bramfordian series. The implemental types are also much more varied and advanced than those of the latter specimens, and comprise rostro-carinates, points, racloirs, scrapers, cores, etc.

(4) *Whittonian.* The Whittonian specimens are a small group, found chiefly in Coe's pits, Bramford, and Bolton and Co.'s brick-field, Whitton, Ipswich. The colour of the majority of the flints is an unusual speckled yellow, and they exhibit very slight signs of rolling and striation. A few rostro-carinates are present in this group, but the greater proportion of the artefacts are racloirs, with one or two scrapers.

(5) *Thoringtonian.* The Thoringtonian specimens equal, approximately, the Boltonian in number, and are found chiefly in the pit at Thorington Hall, Wherstead, near Ipswich, and in the cliffs at Bawdsey, Suffolk. The prevailing colour of the flints is a dense white, or cream, while some of the specimens are patinated blue. The majority of the flints are only slightly rolled and striated, while some are unabraded. Rostro-carinates are rare, while the greater number of the artefacts, which exhibit considerable skill in their manufacture, comprise points, racloirs and scrapers.

(6) *Henleyan.* The Henleyan specimens are a very small group of unpatinated, unabraded, and non-striated artefacts, found chiefly in Bolton and Co.'s brick-field, Ipswich. The predominant type is a skilfully made racloir, and from the condition of these specimens it is legitimate to infer that they were actually made at the site of discovery. No rostro-carinates are present. The titles I have given to these various eolithic industries are based upon the names of the actual pits where the specimens were found, or upon those of the immediate neighbourhood of the excavations, and it is to be hoped that they will pass into general use as have those given to the palæolithic cultures—Chellean, Acheulean, Mousterian, and so on. An examination of the groups of English eoliths must impress unbiased and competent observers as representing a slow but definite evolution of flint implements, and as forming the probable and necessary background to the earliest palæolithic cultures. It has been shown[3] that the eolithic points of the Kentian industry developed into the rostro-carinates, and these into the earliest palæolithic hand axes, and it may well be that the Stone Bed beneath the Norwich Crag in which the latter are found is the geological successor in Norfolk to the Suffolk Bone Bed in which the eoliths occur. The chronological succession of the industries from beneath the Red Crag is irrefutably established by the evidence afforded by the re-flaked specimens, while the difference in technique employed in the various pre-Crag periods seems manifest. I do not think it desirable to place the artefacts found at two superposed occupation-levels in the Red Crag at Foxhall, Suffolk, in the eolithic period. The Crag itself, as distinct from the Suffolk Bone Bed beneath it, is, I think, best regarded as of Early Pleistocene age, and it is possible that the Foxhall specimens are of the same period as those of Group 5 from the base of the Cromer Forest Bed[4] and referable, therefore, to the beginning of lower palæolithic times.

OBITUARIES

Prof. E. Barnes

PROF. EDWARD BARNES, professor of chemistry at the Madras Christian College, died suddenly at the end of May 1941 at the early age of forty-nine. During the past twenty years Barnes had developed a passion for botany and utilized every opportunity for the pursuit of his hobby. He spent most of his holidays making extensive tours in the hills of South India, and even during a stay of a few days in Ceylon, when returning from leave in England, he managed to find a new species of Arisæma. Assisted by his wife, he made a close study of the vegetation in the vicinity of his camps, and this assiduous research led to the discovery of a number of new species of herbaceous plants, all of which were described in either the *Kew Bulletin* or the "Icones Plantarum".

While collecting the majority of the species he encountered, he devoted particular attention to the genera Arisæma (Araceæ), Impatiens (Balsaminaceæ)

and Sonerila (Melastomaceæ). Especially in connexion with the first-named he recorded many observations of interest, including some with reference to their relation to the insects that effect their cross fertilization. Some of his conclusions were published in the *Journal of the Natural History Society of Bombay*.

His herbarium specimens (a considerable number of which, including all the type-specimens, were presented to and are lodged in the Kew Herbarium) are particularly well selected and preserved; many retain their natural colours and some are so prepared that all the floral parts can be seen without further dissection.

Barnes's friends, besides feeling the loss of a good companion, are convinced that botanical science has been robbed of one who would have brought much further knowledge of plant life to light.

C. E. C. FISCHER.

WE regret to announce the following deaths:

Dr. John Ball, technical counsellor to the Survey of Egypt.

Mr. Claude Hutchinson, C.I.E., formerly Imperial bacteriologist, Pusa, lately chief scientific adviser in India to Imperial Chemical Industries, Ltd., on August 2, aged seventy-two.

Mr. C. Pendlebury, senior mathematical master at St. Paul's School during 1877–1910, honorary secretary of the Mathematical Association during 1886–1936, on August 18, aged eighty-seven.

NEWS AND VIEWS

Comenius Tercentenary Commemoration

JAN AMOS KOMENSKY (COMENIUS), the great Czech educational pioneer, author of the "Janua Linguarum", "Didactica Magna", and many other books, paid a visit to England in 1641. His resolute internationalism and his plan of a "Pansophic College" for co-operative scientific research were among the influences leading to the formation of the Royal Society, which, in its first form, the Invisible College, began its meetings in 1649. Unfortunately, the Civil War, and his failure to find in any other country a patron able and willing to carry out his schemes, postponed the realization of his ideas, which he never lived to see.

On October 24, a meeting will be held in the Senate House of the University of Cambridge at which the following discourses will be delivered: President Benes, "Comenius's Plans for Peace Leagues and his Place in History as a Great European"; Mr. Jan Masaryk (Foreign Minister of Czechoslovakia), "Comenius as an Educational Pioneer"; Prof. J. D. Bernal, "Comenius's Visit to England and the Foundation of the Royal Society"; Prof. Ernest Barker, "The Debt of Europe to Comenius and to Czechoslovakia". These, together with contributions from other distinguished scholars, will afterwards appear in the form of a small commemoration volume. Official representatives will, it is expected, be present on behalf of the embassies and Governments o Czechoslovakia, the U.S.S.R., Poland and Yugoslavia, the Board of Education, the Royal Society, the British Council, the Moravian Church (of which Comenius was a bishop), etc. The Tercentenary Committee consists of the Vice-Chancellor of the University of Cambridge, Mr. H. Butterfield, Prof. G. Haloun, Sir William Dampier, Prof. G. R. Owst, Mr. B. W. Downs and Dr. J. Needham, to the last-named of whom, at Caius College, any communications regarding the tercentenary should be addressed.

Photo-Electric Devices for Detecting Incendiary Bombs

THE British Standard Specification (A.R.P. Series) for the performance of photo-electric devices for the detection of incendiary bombs forms one of a series of standards prepared by the British Standards Institution at the request of the Ministry of Home Security (*BS/ARP* 60. British Standards Institution, 28 Victoria Street, London, S.W.1, 6*d*., post paid 8*d*). The alarm is normally intended to be given within or near the premises so equipped for the purpose of warning fire-watcher parties, and is not primarily designed to call the public fire-fighting services or to bring automatic fire-extinguishing equipment into action. The photo-electric devices may be of various types incorporating light-sensitive cells, including (*a*) photo-conductive cells, (*b*) photo-emissive cells, and (*c*) photo-voltaic cells. The alarm device must be battery operated and give an audible signal which may, if desired, be supplemented by a visual signal. The power supply to the alarm circuit must be obtained from a battery the nominal voltage of which shall not be less than 3, and this battery must be used exclusively for the alarm circuit. The methods of carrying out type tests, routine tests and the test after installation are described.

An appendix deals with the photo-electric cells commonly in use, namely, the selenium cell, the alkali cell and the rectifier cell. The term 'photo-electric cell' is sometimes used as a generic term to embrace these three main types of cell, together with all other devices capable of producing changes in an electric circuit by the action of light. It is preferable, however, to distinguish more clearly between the three main types. The selenium cell is the most common example of a class of semi-conductor the ohmic resistance of which is a function of the illumination to which the cell is exposed. Such cells are termed 'photo-conductive cells'. In the alkali cell there is an electron emission across a vacuum or gas-filled space, and such cells are termed 'photo-emissive cells'. When the term 'photo-electric cell' is used in a restricted sense, it usually relates to the photo-emissive class of cell. The rectifier cell belongs to a class which is termed photo-voltaic. Such cells consist of a contact between a metal and a semi-conductor, and one of the most efficient semi-

conductors for use in rectifier cells is selenium. Such cells must not be confused with selenium cells in the photo-conductive class.

Myths of Sun Snaring

In a recent paper ("Oceanic, American Indian, and African Myths of Snaring the Sun", by Katharine Luomola, Bernice P. Bishop Museum, Bull. 168; 1940) the author has made an exhaustive study of myths and magical practices for sun snaring which she has collated and analysed. In each section the stories and processes are given in full and then compared with each other and with those of the other sections, and by this method possible centres of diffusion have been determined. There are striking similarities in some of the myths, for example, in the use of a woman's hair as a snare, which tale, with variations, seems to have diffused in Polynesia from the Society Islands, and in North America from the Lake Superior Ojibwa and the Menominee.

Other myths show less resemblance and could easily have arisen independently, and on the whole the author's conclusion is that the evidence is not sufficient to show a common origin for these two areas. Similarly with the African myths and magical processes; although there are parallels between the Nandi and the Melanesians in knotting grass to retard the sun, this alone can scarcely be sufficient evidence of contact. As regards cat's-cradles, the author is mistaken in her statement that these are forbidden by the Iglulik during the winter; according to Jenness, this is the season at which they are allowed. There are two distribution maps, numerous authorities are quoted and the paper forms a useful addition to the study of sun myths.

Canadian Aerial Forestry for Burma

In the *Indian Forest Records* (Silviculture (New Series), 4, No. 1; Govt. of India Press, New Delhi, 1940), Mr. J. D. Braithwaite of the Burma Forest Service discusses the great advance which has been made in discovering comparatively cheap methods of applying aerial survey to solve forestry problems, and considers that these methods should be applicable to Burma. Burma started before India in making use of the aeroplane in connexion with the forests, for during 1924–25 the Delta and the Heinze Basin were both surveyed from the air with good results. Mr. Braithwaite relates that immense strides have been made in Canada in air work in the last ten to twelve years—strides which were to a great extent unknown even to the United States alongside. Their chief importance is their practical nature and cheapness as compared with methods in force in England, or, to quote an example given by the author, Germany, where he remarks "the scientists have got hold of both the photographic and mapping operations to such an extent that a very expensive and highly trained staff is needed to work the very delicate and costly machinery that has been painstakingly developed".

Obviously this would be as useless as impossible for the great areas of the Empire forests. It is in this simplification and cheapening of methods to which Canadian investigators have directed themselves, and Mr. Braithwaite during a visit to Canada for the purpose was able to study the work with thoroughness, as his monograph well displays. Some of the forestry problems of chief importance in which aerial survey can give the greatest assistance are (1) the problem of mapping small plantations; (2) the thinning of young plantations and an examination of the degree of stocking; (3) stockmapping, and the distinguishing of individual species in a mixed forest, from the air.

Horticulture of the Amaryllidaceae

The title of the periodical *Herbertia*, though somewhat concealing to the uninitiated, covers a concentrated scientific approach to the horticulture of the Amaryllidaceæ. It appears as the yearbook of the American Amaryllis Society (from the Editor, Dr. H. P. Traub, Orlando, Florida, U.S.A.). Vol. 7 for 1940 announces the description of two new species, *Amaryllis aglaiæ* and *Zephyranthes Fosteri*; it discusses the phylogenetic position of several groups within the natural order, and acts as a genetic record for the origins of many hybrid introductions. The first part of a large-scale review of the breeding and testing of day-lilies (Hemerocallis) further indicates the sources of various characters which have been combined to form clones of proved horticultural excellence.

A paper by Dr. A. B. Stout correlates the vigour of shoot growth with the origin of a clone, and W. M. James outlines briefly the methods of growing Alstroemerias from seed. Germination is optimum when the seed has been subjected to a temperature of 77° F. for two months, followed by one month at 50° F. The same author has also a short paper on the best conditions for harvesting and storage of amaryllid bulbs. A method of preserving herbarium specimens in their natural colours by drying in sand is described by Dr. H. P. Traub. *Herbertia* ministers to the practical cultivation of its particular group of plants; it also maintains a welcome personal character, for the pioneers of Amaryllid culture are described in biography. The volume is withal an excellent example of what yearbooks should be.

Celluloid for Cycle Accessories

One of the most interesting features in the development of the British bicycle industry during the past sixty years has been the growth of a group of specialist manufacturers whose products have had a great deal to do with the success of the modern British lightweight bicycle in the markets of the world. The *Export Trader* of August says that by careful experiment, continuous research and insistence on high quality they have produced components, parts and accessories for bicycles in steel, rubber, celluloid and other materials which, because of their lightness combined with their strength and durability, have enabled British cycle manufacturers

to turn out machines better than those of any other country.

Among this group of specialist manufacturers is the firm of Bluemel Bros., Ltd., Woolston, near Coventry. At an early stage in the firm's history the brothers Bluemel realized the advantages of the application of celluloid with its inherent lightness and freedom from dust to bicycle design, and now a large number of the accessories which the firm manufactures are made of this material. The celluloid type tyre inflator was a great success from the start. It was able to withstand the rough and tumble of every-day usage without becoming dented and thus put out of service. Its smooth and easy action is also another commendable feature. Later the Company started to produce celluloid chain covers for cycles. Celluloid mudguards have also been very successful. Quickly detachable fittings of light construction enable the rider to attach or remove them without interfering with the wheels. Celluloid cycle handles are coated with strong adhesive and only require moistening before placing on the handlebars. The 'Cushion Grip' rubber handle is very comfortable to use, although, unlike sponge rubber, it does not absorb moisture.

Recent Earthquakes

TWENTY well-established earthquakes were registered at the Swiss observatories in March 1941, and nineteen in April 1941, according to the bulletins just received. Some of these were distant earthquakes mentioned previously in NATURE, but some were local. On March 12 an earthquake was felt with intensity 4 on the Rossi-Forel scale at Lokalstoss in Andermatt. On March 28 an earthquake with intensity 3–4 was felt in Canton Graubunden, its epicentre probably being south-east of the Ortlergruppe. On March 29 an earthquake with its epicentre near Oberwallis was felt in Visp with intensity 4. The only local shock in April was apparently on April 6 and had an epicentre near Val d'Anniviers and was felt in Vissoie with intensity 5.

THE Jesuit Seismological Association of St. Louis has recently determined the epicentres of two strong earthquakes. The first shock was on January 5, 1941, with tentative calculated epicentre 2·0° S., 123·7° E. and T_0 18h. 46m. 44s. G.M.T. The depth of focus was considered somewhat deeper than normal, and this is not surprising since earthquakes from this region are often from a deeper than normal focus. The epicentre is near the centre of the island of Celebes in the Dutch East Indies. The second was on February 9, 1941, and was felt at Eureka, California. The tentative epicentre was calculated to be at 41·1° N., 125·5° W. with T_0 9h. 44m. 5s. G.M.T. and depth of focus probably near normal. It probably had the same epicentre as the earthquake of January 31, 1922, which has been described by J. B. Macelwane, S.J. (*Bull. Seis. Soc. Amer.*, 13, 13; 1923). For both earthquakes complete readings of seismograms from several American observatories are given.

Theodor Kocher (1841–1917)

PROF. THEODOR KOCHER, one of the most famous of recent scientific surgeons, was born on August 25, 1841, at Bern, where he received his medical education and qualified in 1865. After a postgraduate tour abroad he returned to Bern, where he served as Lueck's assistant and succeeded him as professor of surgery in 1872. Though there is scarcely a branch of surgery to which he did not make some valuable contribution, he is best known for his work on the thyroid gland, for which he was awarded the Nobel Prize in 1911. In 1878 he was the first to excise this organ for goitre, and afterwards performed this operation on more than two thousand cases. At an early stage of his career he recognized the value of antiseptic methods, which he was the first to introduce into Switzerland. He was one of the founders of abdominal surgery, especially as regards operations on the stomach, gall-bladder and rectum. His name has been given to a method of reducing dislocation of the humerus, an operation for inguinal hernia and numerous instruments. Throughout his life he paid constant attention to anatomy and operations on the cadaver.

Kocher's principal publications were the "Operationslehre", which was translated into English, French, Italian, Spanish and Russian, lectures on surgical infections and forms of fracture. He was also the author of works on diseases of the testis and on gunshot wounds, as well as of numerous contributions to periodical literature. He received many honours in his own country, including the presidency of the Bern Medical Society, the Swiss Medical Committee and the Swiss Society of Pathology, as well as foreign distinctions such as the honorary fellowship of the Royal College of Surgeons of England and the presidency of the German Society of Surgery and of the International Congress of Surgery held at Brussels in 1905. In 1912 in honour of the fortieth anniversary of his appointment as professor he was the recipient of a *Festschrift* which formed the 116th volume of the *Deutsche Zeitschrift für Chirurgie*. He died after an abdominal operation on July 27, 1917.

Announcements

THE following appointments and promotions in the Colonial Service have recently been made: R. W. Ford, veterinary officer, Gold Coast; T. T. Threlkeld, veterinary officer, Jamaica; B. D. Evans (assistant director), director, Royal Observatory, Hong Kong.

FIVE hundred bottles of blood serum prepared at the University of Toronto in a laboratory furnished by the Canadian Government are being sent to the National Institute for Medical Research, London, for the treatment of air-raid casualties.

BY an Order of the Committee of Privy Council, made after consultation with the Medical Research Council and with the president of the Royal Society, Mr. E. Rock Carling (senior surgeon to the Westminster Hospital) and Prof. S. P. Bedson (professor of bacteriology in the University of London) are appointed members of the Medical Research Council, in succession to Prof. G. E. Gask and Prof. W. W. C. Topley, who retire on September 30.

LETTERS TO THE EDITORS

Terminology of Relative Growth-Rates

It is generally agreed that the study of the rates of growth of parts of organisms in relation to the rates of growth of the wholes or of other parts is one of the most fruitful ways of advancing our knowledge of ontogenetic development. But these biological processes have stable end-results. Organisms differ among themselves in size, weight, proportions, etc., when at corresponding stages of their life-cycles. These differences are often expressible by the same, or similar, relations to those which describe developmental relative growth. Their study is one of the most fruitful ways of advancing our knowledge of phylogenetic development.

Satisfactory and generally accepted terminology for these comparisons has not yet been quite achieved. Some time ago, in these columns, Needham and Lerner[1] proposed that for ontogenetic relative growth the term *heterauxesis* should be used, with *isauxesis*, *tachyauxesis* and *bradyauxesis* to denote the cases where the growth of the part is at the same rate, or faster, or slower, than that of the body as a whole. The older term *allometry* was suggested for comparisons of phylogenetic character. It seems, however, that it is in the opinion of many desirable to have a covering term for both these comparisons, and this being so, we wish to suggest here that *allometry* be the covering term, and *allomorphosis* the term for phylogenetic comparisons. This indicates that all these differences are quantitative, but that on one hand they concern differing rates of growth in the individual, and on the other they concern different (morphological or chemical) patterns brought about by previous heterauxetic growth in the completed individual of different groups.

The following definitions may therefore be given:

(1) *Heterauxesis*, the relation of the growth-rate of a part of a developing organism (whether morphological or chemical) to the growth-rate of the whole or of another part; a comparison between organisms of the same group but of different ages and hence sizes.

(2) *Allomorphosis*, the relation of parts of organisms at some definite age to wholes or parts also at some definite age, but of different groups (races, varieties, species, genera), for example, egg-size or hatching-weight to adult size or weight.

(3) *Allometry*, ontogenetic heterauxesis and phylogenetic allomorphosis.

Ultra-violet Rays and Their Variations

WIRELESS operators have observed that the strength of signals received by them from distant stations varies from time to time. There is a secular variation which Sir Edward Appleton has shown coincides in general with the solar cycle[1]; there is an annual variation depending on the season; and there is a daily variation in which sunrise and sunset play a prominent part. These variations are, with high probability, effects of the ionization of the upper atmosphere and this ionization is, in its turn, produced by the ultra-violet rays from the sun. Observations of ultra-violet rays are of considerable interest in this connexion and have been carried on in one or two places for a number of years.

In order to allow for the effects of the lower atmosphere in absorbing radiation, Dr. Pettit's method[2] has been adopted in the following way.

Two groups of rays have been observed, one in the ultra-violet of wave-length around 3600 A., and the other in the visible region around 4500 A., and by taking the *ratio* of these the influence of the lower atmosphere may be neglected as a first approximation.

It has been found that there is a variation of this ratio which is in sympathy with the solar cycle[3]. There is also a variation in which there are high values in winter and lower values in summer; and now recent observations made daily, every three hours, show a variation of the ratio in which values are high at sunrise and sunset and low at midday. Curves of these seasonal and daily ratios of ultra-violet and daylight rays agree closely with each other both in form and magnitude.

Experiments on the reflexion of electromagnetic waves from the upper atmosphere show that the Kennelly-Heaviside ionized layer increases in density from winter to summer and decreases from summer to winter; in the same way there is an increase of density from sunrise to midday and a decrease from midday to sunset. These variations readily explain the fluctuations of ultra-violet rays treated as a percentage of the daylight rays. Thus, of the ultra-violet rays supplied by the sun, a part of their energy will be absorbed in the process of ionization, and the remaining part will pass on to the surface of the earth, while the visible rays which do not ionize the air pass to the surface of the earth without losing energy in this way. Now ionization by the ultra-violet rays will be approximately proportional to the altitude of the sun, and when this is high as it is in summer, or at midday, the absorption of ultra-violet rays in ionizing will be a maximum, and consequently at these times the percentage of ultra-violet radiation reaching the surface of the earth will be a minimum. Similarly, when the solar altitude is least, the percentage of ultra-violet radiation reaching the earth will be largest. This is in agreement with observation.

Thus the behaviour of ultra-violet rays and the behaviour of electromagnetic waves both yield, although in different ways, evidence of ionization in the upper atmosphere.

After-burning of Carbon Monoxide: Spectroscopic Evidence for Abnormal Dissociation

IN recent papers[1,2] I have discussed the cause of the after-burning and latent energy of the carbon monoxide flame in relation to the flame spectrum, and have given estimates of the lives of the vibrationally activated molecules which are formed. It was also suggested that the high vibrational energy of the newly formed molecules might result in a large amount of dissociation. Since I communicated these papers, David, Leah and Pugh[3] have published some experiments on latent energy and dissociation in flame gases which give striking support to my suggestion.

The theory of the later stages of the combustion of carbon monoxide may be summarized as follows:

(*a*) Since the dissociation products of a normal carbon dioxide molecule are not normal $CO(^1\Sigma) + O(^3P)$, but electronically excited $CO\ (^3\Omega) + O(^3P)$, the formation of normal carbon dioxide from normal carbon monoxide and oxygen must require an electronic rearrangement in the newly formed carbon dioxide molecule.

(*b*) The excited state of carbon dioxide, before the electronic rearrangement, is probably triangular, while the normal carbon dioxide molecule is known to be linear. Hence the electronic rearrangement, whether occurring by radiation or on collision, will result in the newly formed molecule acquiring a large amount of vibrational energy owing to the sudden change in shape.

(*c*) This excess vibrational energy will, if the gases are pure, persist for an appreciable fraction of a second. In the presence of moisture, however, the excess energy will be quickly transformed into thermal energy.

(*d*) For the carbon dioxide molecule the transverse vibration ν_2 and the symmetrical vibration ν_1 have frequencies which satisfy the relation $\nu_1 = 2\nu_2$ to a very close approximation. This degeneracy may result in resonance between the two vibrations and transfer of energy from one form to another, and thus may result in dissociation of the molecule if its vibrational energy content is sufficiently high.

This theory appears to explain many of the peculiarities of the combustion of carbon monoxide, such as the effect of moisture on flame speed and flame temperature, the effect of drying in increasing the infra-red radiation[4] from explosions, and the failure to observe the infra-red band at 14·9 μ.

In the recent experiments by David and his colleagues it has been shown that temperature measurements of flames made with wires coated with quartz indicate an abnormally high dissociation of the CO_2 molecules, this being greatly in excess of the dissociation expected at the flame temperature. If the newly formed carbon dioxide molecules are vibrationally activated, as indicated by the theory above, they may be regarded as having a very high effective vibrational temperature, this being much greater than their effective translational temperature. Since it is the vibrational temperature which determines the dissociation of the molecules, it is to be expected that the vibrationally excited molecules formed by the combustion will show an abnormally high dissociation.

The afterglow of carbon dioxide in a discharge tube[5] and the after-burning should both be regarded as manifestations of this dissociation, the usual flame spectrum being emitted during the recombination processes following the dissociation. The emission of light during the after-burning or afterglow should not be regarded as due to emission from activated (metastable) molecules, which have not sufficient energy to give a spectrum in the ultra-violet[6], but as due to the flame of gases which are recombining following the abnormal dissociation. Increase of pressure will increase the light emission from the after-burning gases by altering the dissociation equilibrium; Prof. A. C. G. Egerton points out that this is supported by observations of the increased luminosity at the centre during explosions in closed vessels when the pressure wave travels back through the burnt gases.

"White Horses"

THE behaviour of secondary waves riding on the larger primary ones does not seem to have been taken into account in the theory of wind-formed sea waves. From the geometry of trochoids, surface water particles at the troughs on either side of the crest of a secondary wave will close up when this wave is riding on the crest of a primary one, and open out at its trough. The energy of the secondary wave will squeeze up and disperse accordingly; and height, and so steepness, will be affected not only on that account, but also because the relationship of height to energy will change owing to the vertical acceleration of the water caused by the primary wave.

Thus, if L, H, S, E denote length, height, steepness and energy per sq. ft. of water surface of the primary wave, S being taken as $H \div L$, and l, h, s, e apply to the secondary wave, l will range from $l \times (1 - \pi S)$ at crest, to $l \times (1 \times \pi S)$ at trough; e from $e \div (1 - \pi S)$ to $e \div (1 + \pi S)$; and W from $64 \times (1 - \pi S)$ to $64 \times (1 + \pi S)$ lb. per cu. ft. Therefore, as $e = W.h^2 \div 8$, h will range from $h \div (1 - \pi S)$ to $h \div (1 + \pi S)$, and s from $s \div (1 - \pi S)^2$ to $s \div (1 + \pi S)^2$. It will be noticed that this deformation is independent of the steepness of the secondary wave, and of whether that wave is moving with or against the primary one.

It is commonly assumed that 'white horses' are due to the wind blowing off the tops of the primary waves, and that may be partly true. But they are apt to persist for some time after the wind has completely dropped, so must also be accounted for by the steepening, and consequent breaking, of secondary waves when the crests of the primary ones are passing under them. To reduce the problem to figures, let L, H, S be 200 ft., 5 ft. and 0·025, and let l, h, s be 20 ft., 2 ft. and 0·10, on the average. s will increase from that average value to almost 0·12, which is not far off Wilton's theoretical limit[1] of 0·13, a figure which may not necessarily always be attained, for waves have but a small margin of stability as they approach breaking point.

Further, it seems to be common experience that a nasty lop gets up with great rapidity when wind starts to blow against a swell, and this may be accounted for by the effect described.

The above applies to deep water. When the primary waves run into shoal water, the horizontal movement of the water particles is increased, and so the length and height of secondary waves, when they are riding on primary crests, are respectively decreased and increased to greater extents than before. There will only be secondary waves when there is an onshore wind, and then these waves will break more easily after the primary ones feel the bottom than they did before; and when they do break they will create disturbances which may initiate the breaking of the primary waves. This may be an explanation of the conclusion arrived at by Gaillard[2], who made many observations to determine the ratio of D (depth of water) to H necessary to cause breaking. He found that "for a given locality and given slope [of bottom] variations in the ratio of D to H appeared to be due almost entirely to the direction and force of the wind", and that while with a strong onshore wind the ratio might be 1·25, an offshore wind reduced the figure to 0·72.

Transmission of *Leishmania tropica* by the Bite of *Phlebotomus papatasii*

SANDFLIES *Phlebotomus papatasii* ♀ were infected with *Leishmania tropica* by feeding through a membrane on a suspension of flagellates in 3 parts of 2·7 per cent saline and 1 part inactivated defibrinated rabbit blood.

They were afterwards refed on eight human volunteers, of whom five have so far become infected with cutaneous leishmaniasis as a result of bites from twenty-six infected sandflies. Twenty-six infected sandflies produced twenty-eight individual lesions, of which twenty-seven were produced by eleven sandflies only.

This experiment differed from previous negative experiments only in that the sandflies were kept at a temperature of 30° C. and that they were infected by feeding on a suspension containing 2·7 per cent saline instead of normal physiological saline. Full details will be published elsewhere.

Evolution in the Genus Pæonia

THE genus Pæonia has three main centres of distribution and diversity: in the Mediterranean and Black Sea basins, in the Far East from Tibet to Japan, and in North America. From my own and previous chromosome studies[1,2,3], I find that in these separate regions it has undergone three different methods of species formation, all the time working with the same haploid set of five chromosomes.

In the Mediterranean area are a group of small-range diploids ($2n = 10$). Most of these diploids, apparently by simple doubling, have given rise to large-range tetraploids ($2n = 20$) usually lying to the north of their progenitors. Three of these large-range tetraploids, namely, *arietina* and *peregrina* in the Balkans and Asia Minor, and *coriacea* in southern Spain and Morocco, have no nearly related diploids; apparently their ancestors have failed to survive (see accompanying table).

SPECIES IN PÆONIA

	2x	4x
Europe	*Mlokosewitchii* (Caucasus) →	*Witmanniana* and varieties (Caucasus)
	daurica (Crimea, etc.) →	*mascula* (scattered)
	Clusii (Crete) →	*officinalis*, *humilis* and (N. Mediterranean) vars.
	Cambessedesii (Balearics) →	*Russii* and vars. (Western islands of Mediterranean)
	2 other localized species in Mediterranean 1 widespread in Ukraine	3 other widespread species unrelated to any surviving diploids
Asia	*japonica* (Japan) →	*obovata* and varieties (E. Asia)
	8 other widespread diploids	No other tetraploids
N. America	2 diploids	No tetraploids

It thus seems that the advancing ice had driven the diploid species into Mediterranean peninsulas and islands, and from these isolated fragments of pre-glacial species Europe was afterwards recolonized by more vigorous, or perhaps more adaptable, tetraploids as the ice retreated. The kind of adaptability is shown in some cases to consist in stronger tuber development.

In Asia, on the other hand, there has been no such impassable barrier to movement back and forth, and we find a number of diploid species—some covering a large range, for example, *P. lactiflora* and *P. anomala*—and only one tetraploid, *P. obovata*. This species again is in the north (Manchuria and eastern Siberia), but it seems that the diploids, never having been restricted in population and variation, have themselves been able to meet the opportunity of colonization and to follow the retreating ice northwards.

In the smaller territory of California and Oregon a smaller population shows yet another system of variation. Only two species are recognized, and both of them are true-breeding diploid hybrids of the kind known in Œnothera. Instead of having five bivalents at meiosis they have rings of six, eight or ten chromosomes[3].

Thus in the three regions Nature seems to have carried out an experiment in variation and selection which helps us to understand how different conditions, partly external and partly perhaps internal, can lead to different methods of evolution in members of one genus.

I wish to thank Major F. C. Stern for much of the material on which this investigation was made. All the details of the geographical distribution will be found in his forthcoming monograph[4].

Defence of Source of Food by Bees

IT is well known that worker bees defend their hives against individuals from other stocks. So far, however, there seem to be no reports of bees defending their feeding grounds. The following observations indicate such behaviour. Light pure Italians from a particular stock were fed on a training-table and marked individually according to von Frisch's[1] methods. The food was cane sugar dissolved in twice its weight of water and was poured on sand in a Petri dish. After several days no food was offered for one day. Great numbers of marked bees were observed digging eagerly and persistently in the dry sand and searching the neighbourhood for many hours. Scouting black Caucasians which might have had an occasional drop of syrup on the previous day frequently approached the Petri dish, but although they appeared to be of heavier build, they were invariably attacked and driven away. Of the 217 encounters observed, not a single one was won by the Caucasians. One particular Italian bee which had been treated with hydrocyanic acid the previous day attacked twenty-six times, generally carrying the Caucasians away and stinging at least three of them. Another Italian won twelve duels. If food is offered the pugnacity of the bees is much reduced, but intruders are still chased away.

From a second experiment it appeared that Caucasians similarly trained and marked could equally well defend their feeding-place against I alian intruders. It was remarkable that the same marked Italian bees, which had previously defended their dish so well, were invariably driven away by the Caucasians. It seems that the different smell and the uncertain behaviour of the newcomers arouses the pugnacity of the other group when food becomes scarce. It is possible to train Italian and Caucasian bees simultaneously at the same dish of food. As long as there is plenty of syrup nothing much happens, but when the sand becomes dry a general battle ensues.

In a third experiment Italians from two hives were fed on the same dish and marked differently. When the food became scarce occasional encounters between workers of the two groups were observed, but the fighting was far less intense, and some bees from both hives could be seen digging in the sand side by side for a considerable time. At the same time Caucasian intruders were fiercely driven away, sometimes by the combined efforts of the Italians from different hives. Caucasians from different hives also do not fight one another very intensely. It seems therefore that, in contrast to the defence of the hive, which is defended against all intruders, a bigger racial difference between bees is necessary to induce fighting for the source of food on a large scale. It would be interesting to investigate the behaviour of the offspring of crosses of the two bee races.

Thus collecting bees from a hive take possession of a particular feeding ground and defend it in the circumstances mentioned above against intruders, especially when of a different race, in a way similar to that described for fish, birds[2] and other animals. This result should be borne in mind by anybody attempting to compare the collecting habits of workers of different bee races.

Discovery of *Mysis relicta* in Ennerdale

ON June 19 a single living specimen of *Mysis relicta* was found in Ennerdale Water accidentally trapped in one of a series of funnels which are suspended at various depths to catch the sediment from the overlying water. Although this 'relict' crustacean has been recorded from Loughs Neagh, Erne and Derg in Ireland, this is the first time it has been recorded from Great Britain. It is particularly noteworthy also that it should have been taken in Ennerdale Water as this lake is the only known British locality for another 'relict' crustacean, namely, the copepod *Limnocalanus macrurus* Sars. That there was just a possibility of the occurrence of Mysis in the lake had been realized ever since the discovery of Limnocalanus, but all attempts to obtain specimens had been unsuccessful. The intriguing problems of modification, distribution and geology raised by the occurrence of Limnocalanus in Ennerdale Water have been discussed by Dr. Gurney in his papers on "The Crustacean Plankton of the Lake District"[1], and on "Ennerdale Water: A Problem for Geologists"[2], and the same problems, of course, are still further emphasized by the discovery of Mysis in the lake.

Outside the British Isles these two crustaceans occur, very often together, in many lakes of the Baltic region and in the region of the great lakes of North America, and it seems certain that they have been modified from the marine species *Limnocalanus grimaldi* (De Guerne) and *Mysis oculata* Fabricius since the close of the glacial epoch. Their occurrence, therefore, in Ennerdale Water, some 360 ft. above sea-level, evidently calls for renewed consideration by both zoologists and geologists. It is proposed to endeavour, as soon as practicable under present conditions, to obtain further specimens of Mysis from Ennerdale especially with the view of finding out whether the animals there have developed any distinctive racial characters as compared with other representatives of the species in Ireland and elsewhere.

DEUTERON-INDUCED FISSION*

MECHANISM OF DEUTERON-INDUCED FISSION

By Prof. N. Bohr, For.Mem.R.S.

Institute of Theoretical Physics, University of Copenhagen, May 8

In nuclear transformations initiated by deuteron impact, two types of processes are, as well known, to be taken into consideration. In the process of the first type (process I), the intermediate state is formed by the capture of the whole deuteron by the nucleus; in the process of the second type (process II), the deuteron breaks up during the impact with the result that the proton escapes and only the neutron is taken up in the compound nucleus. As originally pointed out by Oppenheimer and Phillips[1] and more closely discussed by Bethe[2], the cross-section for the formation of the compound system may, in certain circumstances, be considerably larger in process II than in process I. Still, a clear discrimination between the two types of processes by means of ordinary nuclear transformations seems so far to have met with difficulties, and it may, therefore, be of interest to point out that the study of deuteron-induced fission of heavy nuclei offers new possibilities for such a discrimination.

Not only is fission easily distinguished from other possible transformations but, in particular, a certain critical excitation energy different for different nuclei is necessary for fission to occur. Just as regards the excitation of the compound nucleus, the processes I and II differ essentially. While the excitation obtained by process I will be far greater than the neutron binding energy for all nuclei concerned, it will, in process II, on the average be smaller than this energy. Since, for the abundant uranium isotope, as well as for thorium, the critical fission energy is higher than the neutron binding energy, it was concluded[3] that a considerable output of nuclear fission in thorium and uranium could only be expected in processes of type I. Even if, in certain deuteron energy regions, processes of type II should be more probable, they would almost entirely result in a permanent capture of a neutron with formation of radioactive uranium and thorium isotopes with well-known periods.

One of the possibilities of testing these arguments is offered by a comparison between the fission yields in uranium and thorium. This is possible because the probability of fission of the compound nucleus in process I may be estimated with a high degree of approximation. In fact, the excitation energy in process I will not only be sufficient for fission to occur in competition with neutron escape, but even the excitation of the residual nucleus left after the escape of a neutron will be large enough to make a fission quite probable. The total probability for fission of the compound nucleus in such successive transformations was thus estimated[4] to be nearly 1 for uranium and about 0·8 for thorium. These expectations seemed confirmed by the experiments reported by Jacobsen and Lassen[5] who found that the ratio of the fission cross-sections in uranium and thorium at 9-Mev. deuteron energy was approximately 0·7.

In a later discussion of these experiments[6], however, it has been realized that the cross-section for the formation of the compound system in process I, because of the smaller nuclear charge, must be expected to be 25 per cent greater in thorium than in uranium. If the whole fission effect in both elements was due to processes of this type, the theoretically estimated ratio of the fission yields in thorium and uranium should, consequently, instead of 0·8, be about 1·0. The difference between this last figure and the measured value 0·7 seems too great to be explained, unless it is assumed that a considerable part of the effect, at any rate in uranium, is due to processes of type II. A support of this conclusion is also offered by a closer comparison of the fission effects in thorium and uranium for smaller deuteron energies. Thus, in the experiments of Jacobsen and Lassen the fission cross-section for deuteron energies about 8 Mev. is relatively higher in uranium than in thorium, as would be expected if a part of the effect in uranium sets in for lower energy values.

A contribution of process II to the fission effects which is relatively greater in uranium than in thorium may be expected from the fact that the critical fission energy of the compound nucleus for thorium is almost 2 Mev. higher than the neutron binding energy, while, for the abundant uranium isotope (238), the difference is smaller than 1 Mev. Moreover, in the energy region concerned, where the fission cross-section is less than 1 per cent of the geometrical nuclear cross-section, it is possible that a not inconsiderable contribution is due to the lighter rare uranium isotope (235). Since, for this isotope, the critical fission energy of the compound nucleus in process II is about 1 Mev. lower than the neutron binding energy, the probability of fission may, for the low excitations obtained by such a process, be far greater than for the heavy isotope.

To clear up the different questions raised, it would be very desirable that experiments on deuteron-induced fission be extended to a region of greater deuteron energies, and, especially, that such experiments be performed with separated uranium isotopes and with protactinium, for which the critical fission energy of the compound nucleus is nearly equal to the neutron binding energy[7].

FISSION CROSS-SECTION IN URANIUM AND THORIUM FOR DEUTERON IMPACT

By J. C. JACOBSEN AND N. O. LASSEN

Institute of Theoretical Physics, University of Copenhagen. May 8

As reported in a previous note[1], experiments have been carried out with the cyclotron in this institute to investigate the cross-section for fission in thorium and uranium produced by impact of deuterons with different energies. The fission outputs were determined by collecting the radioactive fragments on aluminum foils facing the targets and screened from the deuteron beam. Because of the difficulty of estimating the number of fission processes from the β-radioactivity of these foils, a considerable uncertainty, however, was involved in the determination of the absolute value of the fission cross-section.

In continued experiments, this uncertainty has been reduced by a calibrating procedure in which two thin uranium targets were exposed to neutron impact. One of the targets was placed in a small ionization chamber and the number of fission particles emitted from this target counted by a linear amplifier. The fission particles from the second target were collected on a thin lead foil; the distance between the two targets was sufficiently small to ensure that the neutron intensity was very nearly the same. By measuring the activity of the collecting foil with the same counting arrangement as in the experiments with deuterons, the ratio between the foil activity and the number of fission particles emitted during the irradiation could thus be determined.

Instead of the preliminary value of $0 \cdot 5 \times 10^{-26}$ cm^2 given in the previous note, the measurements thus calibrated gave now the value $(2 \cdot 2 \pm 1) \times 10^{-26}$ cm.^{2} for the fission cross-section in uranium at 9-Mev. deuteron energy. The results found for the variation of the cross-section with deuteron energy and the ratio between the cross-sections in thorium and uranium given in the note remain, of course, unaltered. From the value 0·7 for the last ratio, which agrees with the independent determination by Krishnan and Banks[2], we obtain in consequence $(1 \cdot 5 \pm 0 \cdot 7) \times 10^{-26}$ cm^2 for the fission cross-section in thorium at 9-Mev. deuteron energy.

Details of the experiments are described in a paper in print in the *Communications of the Copenhagen Academy of Sciences* where, also, a description of the cyclotron has just been published[3].

EDUCATIONAL PROGRESS IN THE UNITED STATES

By R. WEATHERALL

ETON COLLEGE

IN recent years, C. V. Good, of the University of Cincinnati, has made a practice of preparing an annual review of educational progress in the United States[1]. In his report for 1940 his method has been to compile a list of educational issues, and then to cite illustrations of the manner in which they are being met. These issues may be summarized as follows:

DEMOCRATIC SOCIETY AND PUBLIC EDUCATION

A great deal of thought is being given to the problem of education for good citizenship in a democratic society. To achieve such an aim requires individuals who have respect for other people, a concern for group problems, and a willingness to use intelligence in problem solving. In dealing with educational matters there is a marked tendency towards co-operative effort. This includes the pooling of ideas by teachers and administrators, and extensive use is being made of joint discussions between teachers and students. In this way the students themselves are being encouraged to ask and answer questions which should help them to evaluate current social, economic and political trends, and to establish helpful relations with other members of the community.

EDUCATION AND THE EMERGENCIES OF NATIONAL DEFENCE

Almost to a greater extent than in Great Britain, teachers and the general public alike in the United States are giving consideration to the repercussions which the present world crisis is having upon the educational field, and to the extent to which by educational means support may be given to the national effort. As the report points out, education is called upon to defend human resources, culture, and American democratic processes, as well as to assist in the material defence of the community and nation. Federal participation in education is extending, and in the service of youth, unification in Federal policy is being brought about in the spheres of health, education, and social welfare.

YOUTH PROBLEMS AND CURRICULUM

Under this heading consideration is being given to the needs of the large number of pupils who will not proceed to college, and who do not require specific technical training. The problem of the responsibility of the community towards young people between the ages of eighteen and twenty-one, who cannot be readily absorbed into industry, is also receiving attention. The United States Employment Service is concerning itself with the adjustment of school-leavers to suitable occupations, and with the best way of enabling young people to enter upon rural life. Other investigations are dealing with the specific problem of Negro students: their development during adolescence, and their status in the existing social and economic order.

To a far greater extent than occurs in the British Isles, public opinion makes itself directly felt in educational policy, and recourse is being made to the

American Institute of Public Opinion. On this point it is interesting to note that a large majority of the public do not feel that education is over-emphasized, although the school-leaving age is some two to three years higher than in England. The large proportion of pupils remaining at school into their middle teens is leading to increased attention being given to individual aptitudes and preferences. As an institution the school is not so directly tied to the college. Freedom from prescribed college requirements has acted as a challenge and a stimulus to the school, and has resulted in a period of great educational growth.

A programme to make science teaching answer the needs of young people has been organized by the Bureau of Educational Research in Science at Teachers' College, Columbia University. This investigation is being carried out on a comprehensive scale, and should lead eventually to conclusions of great significance.

Appraisal and Implementation

As indicated above, educational institutions in America cannot be considered in any way as being tied down by tradition. Not only are they very closely in touch with public opinion, but also continuous discussion is taking place between administrators, teachers, and students as to educational aims and the extent to which they are being achieved. Educational policy thus becomes dynamic, itself the subject of rational investigation, and capable of readjustment from time to time. The Evaluation Study of Bennington College, for example, is intended to be a permanent feature of the College. It is planning to investigate the nature of the College's total educational programme, how this programme developed, the purposes behind the programme, the assumptions underlying the purposes, to what extent these purposes are being realized, and the changes which staff and students consider should be made for the College to achieve its aims more effectively.

Teacher Education

There is little danger that standards among teaching personnel are likely to decline during the present emergency. The spread of examination tests is bringing about some standardization with regard to qualifications, which makes for facility in the selection of candidates. But with the extension of a national system of examinations there arises the risk that examinations may become an end in themselves, not merely the means, and so lay themselves open to commercial exploitation.

The Social Pole of Science and of the Man of Knowledge

The report points out that it is high time that the social responsibilities of scientists and of research workers be recognized and accepted. In the past, emphasis on material production and on the instruments of war has led to technological unemployment and to the partial neglect of problems of human welfare, health, domestic life, and education, with the biological and social sciences starved in deference to the more immediately profitable physical and chemical sciences. Since science and research are determining factors in the destiny of mankind, a social policy for science must be formulated to guarantee that such knowledge will be used for the welfare of society.

[1] *School and Society*, vol. 53, no. 1368.

THE BRITISH COUNCIL

The report of the British Council covering the year ended March 31, 1941*, pays a warm tribute to the work of Lord Lloyd. The Council has recognized two main duties, first, the defensive role in the resistance to and disproval of charges brought against us by German and Italian propaganda and, second, the positive mission of carrying to other countries a knowledge of the contribution which Great Britain has made and still makes towards the science of life and government.

The chief methods adopted by the Council for this purpose are the formation of new or the encouragement of existing British cultural centres abroad, and the Council is now responsible for British Institutes in Malta, Cyprus, Palestine, Egypt, Iraq, Spain and Portugal. Most of the anglophil societies encouraged by the Council are now found in Latin America although before the War the Council was in touch with no less than 250 such societies, many in France, Germany, the Netherlands and Scandinavia. The Council also encourages British schools abroad as well as English studies in foreign schools and universities, and throughout these institutions and elsewhere the knowledge of the English language. Competitive scholarships, valued at £250, are awarded to well-qualified post-graduate students from foreign countries and from the Empire.

Such activities have been inevitably modified by the War. One of the Council's main tasks has been to build up in the premises of the anglophil societies of British institutes and also in foreign universities and other institutions general libraries of English books and to this has been added the presentation of scientific and technical works to specialist libraries abroad. A book export scheme has been initiated to encourage the sale abroad of British books of cultural importance as well as a book review scheme intended to secure the review of British books in foreign newspapers and periodicals.

A small fortnightly publication has been issued since March 1939 under the title *Britain To-day*, containing generally an editorial and three articles written for the foreign reader on subjects which may be expected to be of interest to him. Reference is also made to the work of the Council in regard to films, particularly the commission of documentary films on carefully chosen subjects dealing with British life and achievements and the commission or

* The British Council. Report for 1940–1941. Pp. 176. (London: The British Council, 1941.)

acquisition of films intended for educational purposes abroad or describing scientific or technical achievements which it is desired to make known abroad. An Advisory Scientific Committee has also been formed which it is intended should work in three or more panels, one under the chairmanship of Sir William Bragg dealing with pure science, a second under the chairmanship of Sir Edward Mellanby dealing with medicine, and a third under the chairmanship of Sir William Larke dealing with engineering. Sir William Bragg is also chairman of the Advisory Scientific Committee as a whole.

Previously, the Council's interest in scientific publicity was shown chiefly in co-operation with the British Medical Information Service, the dispatch of a number of scientific and learned periodicals and books abroad including a complete section of the South American Book Exhibition, the preparation of a Spanish hand-book of British industrial practice, in conjunction with the British Standards Institution, and the presentation of equipment to a hospital in Sana'a and to a bacteriological institute in Chile.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Friday, August 29

ASSOCIATION OF SCIENTIFIC WORKERS (at Conway Hall, Red Lion Square, London, W.C.1), at 6.30 p.m.—Open Meeting on "Science and the Soviet Union". (Speakers: Dr. Joseph Needham, F.R.S., Dr. Martin Ruhemann, and others.)*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN THE ELECTRICAL ENGINEERING DEPARTMENT, and a LECTURER IN THE MECHANICAL ENGINEERING DEPARTMENT—The Principal, Heriot-Watt College, Edinburgh (August 30).

HEAD OF THE SCIENCE DEPARTMENT OF THE BLACKBURN MUNICIPAL TECHNICAL COLLEGE—The Director of Education, Education Offices, Blackburn (August 31).

HEAD OF THE ENGINEERING DEPARTMENT OF THE BLACKPOOL TECHNICAL COLLEGE—The Director of Education, Education Department, Caunce Street, Blackpool (September 1).

(a) ASSISTANT ENGINEER and (b) an ENGINEERING ASSISTANT—The Engineer to the River Great Ouse Catchment Board, Elmhurst, Brooklands Avenue, Cambridge (endorsed 'Appointment (a) or (b)') (September 1).

HEADMISTRESS OF THE KENYA HIGH SCHOOL FOR GIRLS, NAIROBI—The Secretary (I.P.B.), Board of Education, Alexandra House, Kingsway, London, W.C.2 (September 1).

LECTURER FOR THE MECHANICAL ENGINEERING DEPARTMENT—The Principal, Merchant Venturers' Technical College, Bristol (September 2).

DEPUTY BOROUGH ELECTRICAL ENGINEER to the Great Yarmouth Corporation—The Engineer and General Manager, Electric House, Regent Road, Great Yarmouth (September 5).

ENGINEER to the Lower Medway Internal Drainage Board—The Clerk to the Board, 71a Bank Street, Maidstone (September 13).

INTERNATIONAL COLLABORATION

A SIGNIFICANT feature of the discussions of post-war international reconstruction during the past year has been the renewed attention given to the League of Nations. Federal Union and other proposals for regional or world federation no longer hold the stage to the exclusion or disparagement of the League. The tendency is rather to re-examine the causes of the League's failure, to appraise more critically its achievements, and, indeed, to regard it as the starting-point of political thought and action in the field of international reconstruction.

Powerful support to that tendency has been given by Viscount Cecil's autobiography, "A Great Experiment"*. Growing recognition of the importance of economic factors in international reconstruction has directed fresh attention to fields in which the League and the International Labour Organisation have been responsible for solid achievements. Even among those who are protagonists of power politics and most sceptical of the acceptance by States of limitations on their power or sovereignty this is appreciated. Prof. E. H. Carr, in "The Twenty Years' Crisis", considers that the best hope of progress towards international reconciliation lies along the path of economic reconstruction, while in his valedictory report to the International Labour Office, Mr. J. G. Winant points the same way with great force.

"The cornerstone of the future", Mr. Winant writes, "is already apparent from the mistakes of the past. Political democracy must be broadened to include economic stability and social security. The waste of resources which has been effectively eliminated in time of war must not be allowed to return once peace has come. An unemployed or poorly employed citizenry is no basis for winning the peace. Even though, at a moment when the survival of democracy is in the balance, priority of production, energy and will must be granted to the waging of the war itself, we must not lose sight of this conclusion from the past. No opportunity to enlarge the social content of democracy must be lost. No opportunity to strengthen the fundamental social and civil rights of the great majority of citizens must be neglected. No opportunity to wipe out the want and the hopelessness of the pre-war period must be ignored. This is not only prudent national defence, it is the tradition of democratic freedom."

Mr. Winant's conclusions from experience of recent years are important. First, he says, it is clear that the democracies cannot survive unless

* A Great Experiment. By Viscount Cecil. Pp. 384. (London: Jonathan Cape, Ltd., 1941.) 16s. net.

they can achieve effective co-operation between Governments and organizations of employers and workers. In this matter of evolving new democratic machinery and institutions, he sees, in the co-operation already developed to further our war effort, the hope of extending the force of democracy everywhere. Secondly, divisions within the ranks of the workers greatly aided the spread of Fascism in Europe, and thirdly, he urges caution in making sweeping generalizaticns on the causes of events. Those who blame social policy for the disasters that overtook France, for example, he considers, are mixing cause and effect, and he sees danger in the tendency to blame workers' organizations for inefficiencies of national economic organization and for military failures.

Mr. Winant's report is both outspoken and optimistic, and both Great Britain and the United States have reason to be thankful that a man of the vision and wisdom revealed in this report plays so large a part in their common counsels. Mr. Winant points to the way in which the War itself, having become the dominant factor in social change, is in some countries tending to promote health measures, social security legislation, and safety precautions as an integral part of national defence programmes. That is true, however, only for the Allied countries, where the democratic ideals are valid, human personality is respected, and freedom of speech, of thought, and freedom to worship as conscience dictates, are possible.

Convinced that the International Labour Organisation has an essential part to play in building the foundations for a peace based on social and economic freedom, Mr. Winant is confident that the Organisation can strengthen the fabric of democracy and make an outstanding contribution to the mobilization of the full strength of democracy. Useful as its machinery may be in helping to adapt existing social standards to war needs and to appraise hastily improvised methods of meeting war strains on the economic and social structure, its value in the preparation for the peace is far greater.

When that time comes, we must be far more ready than we were at the end of the War of 1914–18. Social and economic problems will necessarily be in the foreground, and their solution demands careful technical preparation as well as co-operation between economic and social groups and the Government, in which the experience of the International Labour Organisation and its triparitet machinery will be of great value. It can help to plan for an orderly demobilization of war and defence industry and of military forces, and in the elaboration of the basic principles which must be included in a revised labour code.

In Mr. Winant's mind the International Labour Organisation is not merely a successful experiment. It is an effective instrument for orderly social change, the capacity of which has been proved. That, indeed, is essentially Lord Cecil's verdict on the League's work in economic and social affairs. He pays emphatic tribute to the value of its technical organizations, as well as to the work of the International Labour Organisation, and he points out that the machinery of the League has been of the first importance because it has worked far more rapidly than the old diplomatic methods and because by the pressure of publicity it has thrust aside the obstruction of interested powers.

Shortly before the outbreak of war, the Bruce Committee on the Development of International Co-operation in Economic and Social Affairs proposed the consolidation of these activities under a new general committee of the League designed to be apart from political passions and preoccupations. Lord Cecil, however, insists on the necessity of direct action to preserve peace, to supplement these activities if the fabric of civilization is to be maintained. "The marked success of the League's non-contentious work followed by the recrudescence of European war, is glaring evidence of the mistake made by those who urged that the League could be made to work as a peace-keeping machine without its coercive powers."

Lord Cecil believes that the constitutional union of independent States inside the general framework of the League might help to make men realize that it is only by international co-operation that peace can be preserved. He insists, however, on the fundamental point that no machinery can do more than facilitate the action of the peoples, and unless they and their Governments really put the enforcement of the law and the maintenance of peace as the greatest of national interests, no confederation can compel them to do so. The League experiment failed because the Governments did not do this. Lord Cecil's indictment of the absence of far-sighted and courageous leadership is severe though restrained.

Lord Cecil's volume leaves the reader in no doubt as to the greatness of this experiment in conception and scope, if not in achievement. Whether it can be considered a scientific experiment is another question. None the less, this book,

with its calm appraisal and poise, as characteristic of the scientific spirit as of the judicial mind, which is Lord Cecil's by training, gives us at least a pointer to a scientific approach to the problem, the basis for further experiments on scientific lines in the future. No serious attempt at world co-operation and reorganization can afford to neglect the wisdom and experience gathered in the great experiment Lord Cecil so luminously describes.

Lord Cecil has placed us further in his debt by a pamphlet, "A Real Peace"*, addressed to a wider public, in which he attempts to apply this experience and these conclusions to the problems which will confront us in building a real peace in Europe when hostilities cease, and particularly to the central problem presented by Germany. The pamphlet is more than a reiteration of the conclusions elaborated in the final chapter of "A Great Experiment". He points once again, it is true, to deficiencies of leadership, to the ignorance and short-sightedness which brought the League to failure, and he emphasizes the central lesson that a breach of the peace anywhere is a danger to peace everywhere.

This pamphlet should assist in bringing this lesson home to all, but it is also far more specific. It indicates the importance of the German problem —the necessity of assuming that the peace-loving powers may have to deal with the menace of another German attempt to establish world tyranny by force, and that they must find some way to build up the forces of peace sufficiently to make aggression by Germany or any other power a hopeless proposition. He utters words of caution about the form of international authority which may be required, but considers that any organization for the preservation of peace in Europe should ultimately be open to any country the good faith of which can be trusted and which is prepared to enter into a definite undertaking to collaborate in that purpose with its whole strength.

The advocates of federation commonly place the responsibility for the failure of the League on national sovereignty. Robert Dell, for example, in "The Geneva Racket"†, urges that there is no chance of a permanent peace unless Europe is federated, and asserts his conviction that the abolition of absolute national sovereignty is the essential condition of any solution of the problem of peace. Such critics may well hold that Lord Cecil passes too lightly over the problem of sovereignty, but they must recognize the vital effect of a change in the spirit of the Governments, especially of the Great Powers, for which Lord Cecil contends. Without such a change and the sincere determination to use the League machinery for the purposes for which it was created, no League of Nations will work, however perfect its machinery.

The international authority, Lord Cecil considers, should be based on the representation of States, not of populations, though he would reinforce it by regional groupings ; federation is a matter rather for the future. He touches on the particular problems of minorities and of colonial possessions and mandates, on the necessity for further facilities for peaceful change, and on the three stages by which we must proceed from a state of war to one of established and ordered peace : first armistice, then a conference of belligerents of both sides to consider the actual issues raised by the war, and finally after a reasonable interval a full congress of all interested countries, neutral as well as belligerent, to decide all questions arising in a world settlement.

Lord Cecil does not claim, as Mr. Winant does for the International Labour Organisation, that the League is an instrument true and proved and adapted to our purpose. He does at least see in it an instrument which can be re-shaped, re-forged if need be, to give effective service, if only the spirit and will to use it for its high declared purpose are forthcoming. Progress towards an international society or true world federation may well proceed on two parallel lines : horizontally, through the gradual development of the League towards a federation by progressive limitations of the sovereignty of its members ; and vertically, by way of geographically limited groups or federations in the true sense of the word, established on the basis of affinity of culture, of language, of tradition and of political ideas. To both processes Lord Cecil makes a noble contribution. It is only by education, by creative thought and free discussion that there can come in fullness of time, the wisdom and understanding, the vision and determination which will build on that which remains to us of our heritage, a new League, preserving historic continuity, universality and the unity of the human race, fortified to overthrow all onslaughts of aggression ; and worthy of the sacrifices already incurred in the service of the principles of freedom, truth and justice which it enshrines.

PHYSICS AND THE FUTURE

FOR the majority of citizens science remains inaccessible. It has little or no place in their school life, their newspapers, their cinemas, their radio, or their literature. Although present-day civilization depends entirely on applied science, even the politicians and rulers, who guide our affairs, share this common unfamiliarity with science. Dramatic events like war, however, in which science is misapplied, forcibly direct attention to man's most powerful tool. If the War of 1914–18 was a chemists' war, the present affliction, with its extensive mechanization, radio propaganda and aeronautical developments is a physicists' war. Aerial bombardment alone might almost be called a nightmare of complex physical problems the solution of which would need the efforts of more than the whole of the country's physicists. In the circumstances, a scarcity of physicists is not surprising. The Board of Education is approaching the problem by offering a number of State bursaries chiefly in physics, engineering and chemistry (see p. 251).

But the dearth is world-wide. Of the 4,500 American physicists, about 1,400 are already engaged on war work and 600 more are needed within the next year. One hundred others are needed in essential production industries*. The present solution of letting some of the physicists desert the universities is hampering both the training of future physicists and the production of new physics.

If physicists were wanted in large numbers solely in war-time, and then only to assist in the slaughter of vast numbers of citizens of the world, there are many who would care little for the future of physics. But physics is of vital importance in war-time for the very reason that it will be of vital importance in the future peace. Until the biological sciences have developed, applied physics is man's most powerful tool in dealing with his environment. The fact that civilization is at present misapplying the tool means that, in peace-time, it must be used with redoubled energy both to make good the damage done and also to make up for the time lost during war.

What then are the difficulties in providing an adequate supply of physicists ? In the first place, physics, like all the sciences, is expensive to teach. In many schools the sciences are still apt to be regarded as 'extras' just as in daily life the sciences are outside most men's experience. Of all the sciences, physics is the most expensive. Cost is therefore a highly relevant factor. Money and methods of teaching must be found so that every boy and girl without exception is consciously brought into contact with physical phenomena. Physics will then suffer no neglect, as at present, from ignorance. But not all intelligent boys and girls are potential physicists. Special abilities as well as love of physical phenomena are needed. A mathematical mind, if not technical skill in mathematics, is essential to the physicist in order that he may benefit from the results of mathematical physicists and that he may be able to present his own theoretical problems in suitable form to mathematicians. Then again physics is difficult because it covers not one, but several subjects.

When potential physicists are found they have to be trained. More attention has been given to this process in the United States and in the U.S.S.R. than in Great Britain. Here, expense is again the most significant factor although its influence is subtle. University teaching of physics must be associated with research. But research apparatus is so expensive that little money can be spared for extra non-graduate research assistants and technicians. It is an open secret that a university professor of physics can get more easily the money to pay an extra graduate than a non-graduate member of staff. As a result, junior members of staff are in practice appointed not only for their research abilities but also because their type of research apparatus is already in the department. In a school of research they must in fact play the part of research assistants and technicians, incidentally making apparatus for part of the time which otherwise might be spent in making physics. It would indeed be fortunate if when each new appointment were made research ability and technical experience in a particular branch of physics were combined with equal ability in training physicists.

That no very serious attention is given to the method of training physicists is a result of the comparatively short time of establishment of most physics laboratories. Two other factors are relevant. The reputation of a university physics department as a source of physicists depends upon those few students who, taking to physics as ducks take to water, are almost if not quite independent of the method of training. Then again, until comparatively recently, but few physicists have been used in industry. Conditions have now changed. Physicists whose main task in life is rather to apply than to make physics are, and will continue to be, wanted in increasing numbers. If

* Rev. Sci. Inst., 12, 177–78 and 247–49 (1941).

serious consideration were given to their training, no harm would be done to the few born physicists and much help might be given to the production of physicists who would go out into the world and apply physics to man's needs.

Before the War, the average cost of a university research paper in physics was not less than £300. The average cost of the equipment needed to start work in any one of the specialized branches of the subject was £1,000. An expenditure of £15,000,000 a day on equipment for warfare may make the expense of physics seem paltry. Sufficient evidence of poverty-stricken conditions of some physics research can be seen in such papers as appear from time to time in the *Journal of Scientific Instruments*, where research is described on finding an inexpensive way of carrying out some physical operation for which ready-made but more expensive equipment is already available.

If physicists' contributions to war help to remove ignorance of physics, the money needed for physics in peace-time may be forthcoming. Then will be the time to show that applied physics is as powerful a tool for construction as it is at present for destruction or protection. Even if a university graduate in physics has paid for his training from private sources he will still have cost the community large sums of money. By using his talents together with his training he can repay in service to mankind. Tremendous possibilities lie ahead. One only need be mentioned. At present biology is absent from the education of most men, including physicists. Officially, the physicist knows nothing of life. When this blind spot has been removed, some physicists will feel drawn to biological problems and the wonderful developments of biochemistry will be matched by those of biophysics.

The excellent equipment of the physicists in the United States and the U.S.S.R. should be a lesson not yet appreciated in Great Britain, that, generally speaking, the day of physics done with sealing wax and tobacco tins is past. Physics is an expensive subject and will become more so as each new development is made and applied to revitalize older branches of the subject. But in return for the cost, physicists can and will repay in service to mankind by making and applying physics and by helping to train the next generation. To help recovery from the tragedy of war every scrap of brain-power will be needed. Given the means, physicists can and will play a vital part in this recovery.

IS MARXISM SCIENCE?

Marxism : Is it Science? By Max Eastman. Pp. 343. (London: George Allen and Unwin, Ltd., 1941.) 8*s*. 6*d* net.

MAX EASTMAN is a somewhat odd critic of Marxism. He appears to accept at the outset most of the aspects of Marxism that have made it anathema to orthodox opinion. Not only does he agree with the economic analysis Marx made of the capitalist system, but even with the revolutionary application of this analysis by Lenin. But this seeming agreement covers a fundamental objection to the whole method of Marxism. He is an inveterate opponent of dialectical materialism, not because of its results, but because it represents a type of thinking profoundly different from his own. Max Eastman is a perfect type of nineteenth-century intellectual radical, a believer in common sense and engineering, with a violent antipathy to all forms of philosophy and religion. The book itself represents only one stage in retrogression towards older views. Since it was written, Max Eastman, from being a critic of Marxist logic and philosophy, has moved to a rejection of Marxist economic theory and political ideas.

In this book his fundamental objection to Marxism is that it is religious. Religion he defines as the belief "that the external world, or some power in it, is interested in the interests of men. The religious believer persuades himself that the world is softer than it is, and that we know more about it than we do". And Marxists are religious because "they cherish a belief that the external universe is evolving with reliable, if not divine, necessity, in exactly the direction they want it to go". What he would like instead is a stern belief in the indifference of the world, and what he calls the "engineering approach" to social problems.

"An engineer wishing to convert a given form of society into a more satisfactory one, would begin by making a very rough outline of the kind of society he proposed to build. With that rough blueprint in mind he would examine the existing society, and he would also examine all past societies, and find out what are the forces which control them and the general laws of their change. When he had finished that investigation and acquired that knowledge, he would draw up a procedure or plan of action, a scheme for getting the thing moving (supposing that his investigations had proven it possible) in the direction of his proposal."

The chief sin of Marxism in his eyes is neither its analysis nor its plan of action, but the fact that it mixes analysis with action, instead of keeping them rigidly separate. To prove his thesis he examines the historical origins of Marxism, with particular emphasis on the part played by Hegelian philosophy. Philosophy is naturally to him as destructive as, and far more insidious than, religion. Philosophy to him is a characteristically German rather than Anglo-Saxon way of thinking and acting, and the proof that Marxism is saturated with philosophy is enough to damn it.

There is no doubt that this line of argument will prove highly popular with men of science of the old school. They may be a little shocked by Max Eastman's advocacy of revolution, but will be comforted by the reflection that anti-Marxist revolutionaries are rarely dangerous to the established order and that Max Eastman himself has for years been a most usefully ally to Red baiters.

To anyone who has taken part in the revaluations of science that have been going on during the last twenty years this book will appear simply as a belated landmark of an earlier mode of thought, for the arguments advanced in it are based on a conception of science that has already long been felt to be insufficient—"knowledge derived by the methods of observation, experiment and rational calculation and subject to the practical test of action". This definition, like Euclidian geometry, is true only if we concern ourselves with some small portion of knowledge and action. It is, and will long remain, the working scheme for detailed scientific research ; but if we are concerned with the whole of human experience, its inadequacy becomes manifest. Separate studies, however accurate, do not of themselves provide an integrated picture, and the observer can no longer be kept rigidly separate from the thing observed. This is particularly so in the field of human affairs, where the application of classical science has singularly failed to produce any useful results. Indeed, if we accepted Mr. Eastman's criticism, Marx would be an even greater figure than he was, because he was able to arrive at correct results by using entirely wrong methods.

The aspects that Max Eastman rejects are those which have attracted so many modern men of science to the study of Marxism. In the development of human societies radically new events are continually happening which are not seen, or are seen only with difficulty, in the far slower evolution of cosmic or biological systems. The most striking changes do not appear to be due to any external causes. In human affairs, the problem of the origin of novelty is a central point of interest. Men of science, however, have been content for the most part to ignore all novel features. Some qualify the rejection of their study on the grounds that they lie outside science and in the province of history, where the scientific method was not applicable. Others, without realizing it, evade the issue by appealing to some efficient cause, some life force, which, acting from the outside, brought the changes about. This is a mere deification of ignorance. If these changes are to be tackled scientifically, their origin must be looked for inside the system, in the interaction of its parts. It is this interaction which Marx, using Hegel's terminology, conceived of as a conflict of opposites leading towards a resolution into some new State. The fact that Hegel's opposites referred to a world of pure thought is no more refutation of his system than the fact that Newton's was derived from theology. Both were trying to set down in a language they found appropriate the new relations they had discovered. Marx's opposites, capital and labour, were real enough and engaged in real enough conflict. But if this kind of development by internal conflict could happen in rapidly changing civilized societies, it was very likely that it was happening less rapidly elsewhere ; and, by generalizing the theory of dialectical materialism, Marx and Engels, and particularly the latter, were able to indicate that other conflicts probably underlay earlier changes in human and animal life, and farther back at all critical points of cosmic history.

Critics have objected to dialectical materialism on the grounds that it does not prove anything. But Marx was aware of this, and indeed stated it explicitly. Dialectical materialism aims, not at proving things, but at discovering them. Whether or not it is scientific is an academic question, and depends on whether the word science is to be conceived of narrowly as physical science, or is to include an orderly treatment of the whole range from nebulæ to human society.

The contrast between the old and the new ways of looking at things is most clearly seen in relation to human psychology. One of Max Eastman's major objections to Marxism is its rejection of psychology in the individual sense and the statement that a human being is an ensemble of social relations. Now this central insistence on a human individual is itself a relic of Darwinian controversy, and carries farther back to Descartes's division of body and soul . . . indeed, by neglecting the social aspect, nineteenth-century men of science practically forced the acceptance of a duality between a merely animal body and an æsthetic and moral mind. Marx always rejected this view, and now the modern anthropologists are showing more and more clearly that the uniqueness of man lies not in any of his bodily or mental characteristics as such, but in the fact that he forms part of

a self-perpetuating, self-conditioning community. The centre of interest in Marxism is this community and its development. Human environment is no longer, like animal environment, mainly physico-chemical or biological; it is social: and a social environment is not indifferent to the individuals composing it. If society changes it will always be ultimately because of the desires of the individuals composing it; but it will only be in the general direction of those desires if the individuals who are making the change understand the mechanisms by which change can be brought about. The value of Marxism is precisely the statement of this fact. Any attempt to apply engineering methods to human society, as Max Eastman would like to do, is necessarily to ignore the fact that the very desires of the engineer are conditioned. In so far as he is not aware of this, his aims will themselves be merely a reflection of the crudest aspirations of contemporary society. Indeed, this attitude actually leads straight to Hitlerism. "Mein Kampf" is the perfect illustration of an extremely astute social engineer at work, conscious of his end, conscious of his method, but unconscious of what conditioned his choice of end, or of the probable results of his action in destroying all the things he set out to reach.

The practical burden of Marxism is that effective choice of ends cannot be made without understanding the trends and conflicts of the existing situation. "Freedom is the recognition of necessity." But this does not make Marx a fatalist. When Lenin pointed out that socialism would not occur unless a party worked consciously for its realization, he was closer to Marx's intention than Plekhanov, who believed that it should be left to the automatic working of economic forces.

Marxists say that our actions and our knowledge are never separate, and that we would do well to realize the fact and consciously to combine them. If we imagine that they are separate, we will not only fail to be scientific, but will doom ourselves to a tragic futility.

J. D. BERNAL.

THE STATE OF PHYSIOLOGY

Annual Review of Physiology
James Murray Luck, Editor; Victor E. Hall, Associate Editor. Vol. 3. (Published by the American Physiological Society and Annual Reviews, Inc.) Pp. viii+784. (Stanford University P.O., Calif.: Annual Reviews, Inc., 1941.) 5 dollars.

THE subject of physiology may be likened to a State at the frontiers of which lie several other sovereign States, with which it is in friendly relationship. It is a State consisting of several provinces, and while those inhabiting each province speak the language and appreciate the outlook of those across the frontier, they may be relatively ignorant of the language and customs of those who inhabit other provinces of their own State.

Here, surely, is ripe material for infiltration, with a view to conquest, by neighbouring States, for the liberation of oppressed minorities, and so on. There have, indeed, been Trojan horses (of the friendliest kind)—now it is organic chemistry that holds the key to the mystery of life—or now biophysics—that word to conjure with, that is to be the secret weapon against which none can prevail—or now all riddles dissolve before the heat and light of physical chemistry.

Yet the complex little State carries on, preserving its individuality and its ideals, in spite of all. It is enabled to do this because it has, in reviews of the kind now before us, a sort of parliamentary clearing-house—a talking-house if you wish—where those representing the subjects of its many branches can show what they stand for, and what they have achieved during the period under review. Thus some common understanding and cohesion is maintained and mutual regard kept alive between the different departments of a constantly growing endeavour. It is a pleasure to know that this service to science, which in the old days of international sanity was largely performed by publications in the German language, is, and for some years has to an increasing extent been carried forward in the English tongue, and very largely by American effort.

The present volume, considerably larger than its two predecessors, maintains the high standard of usefulness that was set by them. The contributors are all of high repute, and the outlook of the work is international, in so far as present circumstances allow.

An essential, and perhaps the most important part, of the work is the bibliographies appended to each of the articles. These represent a reasonably full list of the chief publications dealing with the subject of the article; sometimes the list runs into hundreds, and is rarely less than one hundred. The text of the articles is of the nature of a running commentary on the references. The indices of names and subjects, as is usual with American publications, are compiled with care and skill,

As regards the articles themselves, it is obviously not possible to review these adequately. The following bare list of the contents, however, will show that there can be few who are interested in any of the branches of physiology who could fail to find an article that appealed to them :

The relation of bioelectric potentials to cell functioning (G. H. Bishop); the physiological effects of radiant energy (H. Laurens); physiological aspects of genetics (A. H. Sturtevant); developmental physiology (E. Witschi); growth (C. E. Palmer and A. Ciocco); temperature regulation (J. C. Scott and H. C. Bazett); energy metabolism (T. M. Carpenter); respiration (C. F. Schmidt and J. H. Comroe, jun.); physical properties of protoplasm (E. F. Adolph); muscle (W. O. Fenn); the digestive system (J. E. Thomas); liver and bile (W. B. Hawkins); formed elements of the blood (G. M. Higgins); heart (C. J. Wiggers and H. D. Green); peripheral circulation (V. E. Hall); electrical activity of the brain (H. H. Jasper); the autonomic nervous system (D. Sheehan); the special senses, (1) hearing (E. Barany), (2) visual receptors (R. Granit), (3) vibratory sensations and pain (Y. Zotterman); physiological psychology (H. S. Liddell); kidney (L. Leiter); metabolic functions of the endocrine glands (S. Soskin); endocrine aspects of the physiology of reproduction (O. Riddle); reproduction of mammals (M. H. Friedman); bacterial chemotherapy (E. K. Marshall, Jr.); histamine and anaphylaxis (W. Feldberg); exercise (A. H. Steinhaus).

The paper is matt and restful, and the type and make-up of the best.

C. Lovatt Evans.

MOLECULAR SPECTRA

The Identification of Molecular Spectra

By Dr. R. W. B. Pearse and Dr. A. G. Gaydon. Pp. viii+221+8 plates. (London: Chapman and Hall, Ltd., 1941.) 42*s*. net.

To identify a given system of bands in molecular spectroscopy, "it has hitherto remained necessary to search through original papers or to calculate the positions of bands from the tables of derived constants. . . . This task is usually tedious and sometimes impossible to one without considerable experience". Drs. Pearse and Gaydon have compiled tables of data which will facilitate the identification of bands occurring in the region 10000 A. to 2000 A. The data, in tabular form, include the recorded systems of diatomic molecules and a certain amount of data on polyatomic molecules; in many instances the authors have extended recorded data by actual measurements. Data on complex organic molecules and on solutions have not been included, but that in no way detracts from the value of the book since it must be obvious that such a compilation must be limited by two main factors, (*a*) a defined wave-length region, and (*b*) an enforced limitation of the molecular types to be included.

Essentially the work contains two sections, and their contents can be conveyed most conveniently in the concise statements relating to them in the authors' introduction: "The first section consists of a list of the strongest heads of the more persistent and better known band systems of each molecule in order of wave-length, together with information as to origin, intensity in various sources, and appearance. The second section consists of individual lists of band heads for each system of each molecule, accompanied by notes about the occurrence and appearance of the system, the nature of the electronic transition involved, the vibrational assignment of the bands in the system, and references to the sources of the data. The lists are arranged in alphabetical order of the chemical symbols of the molecules."

The arrangement of the tables is exceptionally clear; band heads are listed in groups of five with a space between each group, which makes their perusal less trying than if they had been printed close on each other line after line. In the second section the appearance and occurrence of each band are described in a crisp and complete manner. Thus the book is lifted from being a mere collection of data. The quoted references to original papers have been selected with care and discrimination. That the book has been compiled from the practical point of view is borne out by an excellent short account (10 pp.) of various points, troublesome to the inexperienced, arising in identification and "not usually dealt with in general text-books"; these "practical hints" are an extremely useful feature, as is also the inclusion of fifty selected—and exceptionally well-reproduced—spectrograms.

The authors have accomplished the tiresome work of collection, selection, compilation and arrangement of the vast amount of data with clarity and skill, and the publishers and printers have done their jobs with equal acceptance. Such a book is needed by workers in this field, and the volume under review can be thoroughly recommended.

W. Rogie Angus.

Chemical Computations and Errors

By Prof. Thomas B. Crumpler and Prof. John H. Yoe. Pp. xiv+247. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1940.) 18*s*. net.

THE authors state that their aim in writing this book has been to provide a course on chemical computations and errors for university students specializing in chemistry, and this they appear to have done extremely well. The subject-matter is clear, concise and well arranged, and the reviewer considers that several chapters of the book are admirably suited to the use of sixth-form pupils.

The first five chapters of the book give a simple account of exponential numbers, logarithms, the slide rule, algebraic equations, including the solution of simultaneous equations by determinants, graphical interpolation and extrapolation. The inclusion of historical details in these chapters, and indeed throughout the book, is a very pleasing feature. The chapters on the "Theory of Measurement" and the "Classification of Errors" should be most helpful to the student who takes a serious interest in his quantitative practical work, and he will understand, perhaps for the first time, why there is a difference between a cubic centimetre and a millelitre. A very clear distinction is made between "corrigible errors", that is, those errors for which corrections can be made, and "random errors" for which it is impossible to do anything.

The remainder of the book is mainly concerned with that branch of statistics which deals with the interpretations of discordances in numerical values. Chemistry students will be particularly interested in the statistical treatment of Lord Rayleigh's measurements of the density of nitrogen (pp. 186–188), where it is shown that the actual difference between the mean values for chemical nitrogen and atmospheric nitrogen is 34 times the probable error. This figure, the test shows, provides conclusive statistical evidence for believing that the composition of the two specimens of nitrogen is different.

Suitable problems are set at the end of each chapter and the answers, together with logarithm tables and a useful bibliography, are given at the end of the book.

Elements of Botanical Microtechnique

By Prof. John E. Sass. (McGraw-Hill Publications in the Botanical Sciences.) Pp. ix+222. (New York and London: McGraw-Hill Book Co. Inc., 1940.) 17*s*. 6*d*.

THIS book is the latest addition to the McGraw-Hill series of texts in plant science, which is being steadily built up into an encyclopædia of specialist monographs such as botanists have never before had available. As it follows rather closely on the appearance in the same series of Johannsen's treatise on the same subject, one may first ask what, in the circumstances, is the justification for its publication.

It is neither so comprehensive nor so detailed as the previous work, yet there can be no doubt that it has qualities which earn for it a just title to independence. In the first place it is more genuinely a students' book than Johannsen. It assumes very little preliminary knowledge, and it gets down to fundamentals with commendable practicality. Moreover, its outlook throughout is thoroughly modern and is indicative of that revolution which the commercial production of new organic solvents and plasticizers is rapidly bringing about in the field of microscopy. Old difficulties are vanishing as we begin to know how to build rationally on the empirical foundations laid by the pioneers. Not that we have got far, as yet, and one can foresee that future editions of this book will show many changes as new methods are developed.

One should note with satisfaction the passing away of the period of uncritical microtome worship and commend the sane advice given on when not to microtome. Smear methods, whole-mount methods, maceration (too long neglected), the critical comparison of fixatives: all these are welcome features, even if they are not exactly innovations. The emphasis and the clear illustration given to them in a book for students are certainly novel.

It is refreshing also to see not infrequent comments on expense in an American publication. Is this indicative of another break with tradition ?

R. C. McL.

Dietetics Simplified: the Use of Foods in Health and Disease

By Prof. L. Jean Bogert. With Laboratory section by Mame T. Porter. Second edition. Pp. xi+742. (New York: The Macmillan Company, 1940.) 12*s*. 6*d*. net.

DIETETICS as a subject is peculiar in that its exact study requires elaborate detail and specialized knowledge whereas in practical application no such desiderata are necessary. This at once explains the difficulty of writing a book which should be of service to those who do not need over-much technical knowledge yet are at the same time expected to understand the principles and their employment in everyday life. Students of medicine and domestic science, hospital dietitians, nurses, etc., all need education and help.

Prof. Bogert has tried to plan "Dietetics Simplified" to meet this requirement. That she achieves her aim is shown by the appearance of a second edition three years after the first. She has not, however, felt called on to make extensive alterations but only to bring the data on special points, such as vitamins and food values, up to date.

The scope of the book is planned on generous lines. Elementary nutrition, diet in normal conditions, diet therapy and diet in disease states are supplemented by a series of chapters on cookery of every kind and by careful tables on nutrition figures. The sections on infant feeding and food for the elderly may be remarked on as illustrative of the standard set and attained.

The book is written in an easy attractive style, free from undue technicalities and well illustrated. It can certainly be commended.

MILK PRODUCTION IN WAR-TIME

By Prof. H. D. Kay, O.B.E.
National Institute for Research in Dairying

If from the point of view of human nutrition in war-time the gravest problem is that of providing sufficient calories, the next in importance is undoubtedly that of maintaining at the highest possible level the daily inflow into the national larder of milk—with its unquestioned value in balancing and reinforcing, either for the young or the adult, a diet which may be short of calcium, vitamin A, riboflavin, animal protein, and fat. The adequate solution of the milk problem is dependent on many factors, agricultural, economic, administrative, etc. It is proposed to discuss a few of those in the first of these categories, mainly concerned with feeding and management of the dairy cow in war-time.

It is believed that of all farm animals, the modern dairy cow is the most efficient converter of farm feeding stuffs into human food. This, however, is true only for the animal of medium or higher yield, say, for present purposes, for the animal yielding not less than 500–600 gallons per lactation. It is again fortunate that, as a ruminant and by preference almost entirely a herbivore, the cow, unlike the pig and the hen, does not seriously compete directly with man for the kind of foodstuff he requires for his own diet. In the third place it is fortunate also that as a result of past research, a great deal is now known about the detailed nutritional needs of this highly specialized animal for efficient lactation, though this knowledge, particularly valuable in war-time, is effectively applied on far too small a proportion of our dairy farms.

Quantitatively, the dimensions of the problem of feeding the cow are greater in this than in the War of 1914–18. The dairy cow population at the outbreak of the present War was more than 20 per cent above that of 1914, and there has, if anything, been an upward trend in the last two years. In tonnage, the amount of food required for the dairy herd is not far short of that needed for the entire human population. The average dairy cow weighs about half a ton, and although she will provide each year say 500–600 gallons of milk, containing a dry weight of some 6 cwt. (that is, nearly twice her own dry weight) of first-class human food, she must have, if she is to remain a productive unit, not far short of four tons a year of foodstuff, estimated as dry matter. When this requirement is multiplied by well over three million (the exact number of 'dairy' cows depends on a rather arbitrary definition as between a 'dairy' cow and a 'beef' cow), the huge size of the problem—that of providing some twelve million tons (dry weight) of feeding stuff per annum to secure adequate milk production—is apparent.

It is not generally realized that as much as 80–85 per cent of the total food consumed by the dairy cow (estimated, of course, on a dry-matter basis) is, in peace-time, produced at home, from grazing and from other farm-produced foodstuffs such as hay, straw, roots, kale, silage, etc., these latter for the most part bulky foods with a relatively low energy and protein content and containing a large proportion of indigestible fibre.

For present purposes we may regard the essential food requirements for efficient lactation in the dairy cow as being a sufficiency of digestible nutrients in a bulk which does not exceed the assimilatory capacity of the animal. These nutrients have to provide (*a*) the animal's basal metabolic needs for energy, (*b*) her energy requirements for purposes of muscular movement, digestion and glandular activity, including the activity of the mammary gland and the relatively small amount of material necessary for the day-to-day repair of these tissues, and (*c*) the materials needed for the synthesis of the very considerable quantities of lactose, casein and lactalbumin, and fat secreted by the udder*. The war-time significance of this statement is that the food materials required for (*c*) are rather different in composition than those needed for (*a*) and (*b*). They are richer in protein, and belong mainly to the type of concentrates that was extensively imported from abroad in peace-time.

To obtain the necessary nutrients under (*a*), (*b*) and (*c*) from the ordinary, bulky farm foods is only possible if the yield of milk is small, say ½–1 gallon a day. The capacity and appetite of a high-yielding dairy cow do not allow her to eat sufficient of such bulky foods to maintain her milk yield for very long. She is, like nearly all modern farm animals, in a state of unstable biological equilibrium. Without adequate feeding of concentrated foods she may for a short time continue to secrete large amounts of milk at the expense of her own tissues, but this process will not continue and she will eventually rapidly fall off in yield.

The main problem of feeding for milk production

* The nutrients have also to provide, in most cases, for the growth of the fœtal calf. The main demand here, however, is late in lactation when the milk yield is falling off.

in war-time is to provide the type of concentrated protein-rich nutrients required for purpose (*c*), and that despite the facts that importation of concentrates from abroad is severely cut down, that the by-products of flour milling will soon be both less in quantity and in nutritive value since 85 per cent instead of 73 per cent of the wheat grain will go into flour for human consumption, that there is a shortage of skilled labour on the farm, and that a larger area of farm land is now being used for the production of human foodstuffs such as wheat and potatoes, the by-products of which are not very useful for purpose (*c*).

Without concentrated feeding stuffs, especially in winter, and adequate husbandry the dairy cow would fairly soon revert to a low-yielding animal producing most of her small output of milk from grass in the spring and summer months, and drying off completely in the winter. But alike with the good and the poor cow, feeding presents no problem at all if grass, which if of good quality will contain all the protein needed for purpose (*c*), is abundant. Up to four or even five gallons of milk a day can be produced without difficulty or damage to the cow, and without any supplementary feeding of concentrates, if such grass is available, and fields are grazed in rotation under reasonably efficient conditions of grassland management. In most parts of Great Britain, however, an abundant supply of grass rarely persists for more than three or four or possibly five months of the twelve. For the remaining months both bulky farm foods and concentrates containing sufficient protein are essential, in addition to what the cow can pick up from the pastures, if an average, or better than average, yield of milk is to be maintained. It is particularly in December, January and February, when natural environmental and war-time nutritional conditions both for the dairy cow and for man are at their worst, that human needs for a protective food like milk are at their greatest.

It has been suggested that the nationally most satisfactory war-time plan is for the dairy farmer to go in for summer milk production from grass, and winter his cows in a practically non-lactating condition. The large excess of milk not required for human nutrition during the summer months would then, it is suggested, be dried or "evaporated" and stored, for distribution during the winter season instead of liquid milk.

Even if the requirements of only three winter months were to be met, this scheme would entail treatment of some 240 million gallons of milk, that is, a large increase in our existing milk-drying and evaporating capacity (with plants very busy during the summer and idle during the winter), a very large supply of tin plate or other material suitable for making containers to store the 130,000 tons or more of processed milk, probably an organization to reconstitute the milk in numerous depots, and certainly a formidable change in food habits. Though milk dried or "evaporated" by modern methods and properly packed for storage loses very little of its nutritive value, it is very doubtful indeed whether any extensive change over to summer milk production is either feasible in war-time or advisable at any time.

In present circumstances, the only means by which milk yield may be maintained in winter are: (1) the switching over to the dairy cow of sufficient concentrated feeding stuffs, both those produced at home and those that continue to be imported, from less essential stock such as pigs and poultry, or (2) an increase in quantity and quality of the feeding stuffs grown on dairy farms at home, so that they not only provide all the maintenance rations needed for purposes (*a*) and (*b*) mentioned above, but also meet the higher protein requirements for purpose (*c*).

Alternative (1) is the foundation of the rationing system that was introduced half-way through the winter of 1940–41. By this system the greater proportion of the available concentrates were allocated to dairy cows: farm horses and one or two other categories of essential animals received a sufficient ration, beef cattle were reduced to about 50 per cent of their pre-war requirements, and the small amount left was allocated to pigs and poultry. Alternative (2) is clearly one which needs time to achieve. It means in the first place the improvement in quantity and quality of the grass produced on the farm, an improvement which had in fact begun, if only in a small way, before the War. This entails the ploughing up, appropriate artificial manuring, and re-seeding of worn-out or indifferent pasture, the general improvement of grassland by adequate dressings of lime and phosphates, the use of suitable seed mixtures and nitrogenous fertilizers on selected fields to produce grass one or two weeks earlier in the season and possibly to induce grass to linger for about the same length of time in the late autumn, with a corresponding economy in concentrates. It also means the making of silage in the spring from young grass (the younger the grass the higher the protein content) and particularly in the autumn from aftermath, or from special mixtures of cereals and pulses which have a high protein content, improvement in methods of haymaking, to ensure that losses of feeding value are minimal, the use of green 'soiling crops' such as mixtures of pulses and cereals, or, in warm districts, maize, to supplement the grass supply during the summer and early autumn, the growing of more cabbage and kale to provide green fodder

during the winter months, an additional acreage of peas and beans to provide protein-rich fodder, an increased production of root crops such as swedes and mangolds for winter and early spring feeding, the production of a valuable food, of approximately the same energy value for the ruminant as good hay, from wheat straw (a material not normally used for feeding dairy stock, but which is increased in amount over pre-war quantities) by soaking it with dilute caustic soda solution, the intelligent use both of farmyard and artificial manures. These are all aspects of good dairy farming by which dependence on purchased feeding stuffs will be steadily lessened during the present year and in the future. Many dairy farmers, after the 1941 harvest, will already have achieved this objective of self-support, and the rationing scheme for dairy cows for this winter will undoubtedly be largely based on this fact.

Little has been said about the effect of war-time conditions on milk quality. In general, quality is rather more stable to environmental changes than is yield. If yield falls, then there is normally a small increase in milk fat percentage, as was in fact observed last winter. Insufficient feeding of concentrates, in addition to its depressing effect on yield, is sometimes associated with a diminution in the percentage, of solids other than fat in the milk. On the whole, however, it may be said that the war-time diet of the milking cow will only have quite small effects on the composition of her milk.

Second only in its effects on milk yield to a shortage of feeding stuffs, and much more drastic in its effects in reducing the nutritional quality of milk than any other factor, is udder disease. Even in the sub-clinical stages mastitis produces a marked fall in the compositional quality, and therefore in the nutritional value of milk, together with an appreciable drop in total quantity secreted, and the changes become more serious as the disease progresses.

In peace or in war, until this disease—or group of diseases—is taken in hand on the national scale, these largely avoidable losses will continue to be suffered. Some authorities are of opinion that there has been an increase in udder disease during the last two or three years. This may well be, as with the unskilled labour that has on many farms replaced the pre-war skilled cowman—a process which began before the outbreak of war—early symptoms of the disease are easily overlooked and veterinary treatment delayed until irreparable damage has been done to the udder tissues. An animal even at this stage may continue to secrete a little poor quality milk without requiring supplementary concentrates in her diet, but since the food required for maintenance of a poor or indifferent animal is little if any less than that required for maintenance of a high-yielding cow, the former animal is wasting food if the criterion of milk yield divided by total food consumption is applied. At the other extreme, the very high yielder in war-time is difficult to handle successfully, as she requires highly skilled management and in some cases special foodstuffs, neither of which may be available. The desirable dairy cow in war-time is an animal giving a good, but not an immense yield.

In war-time as in peace-time, culling of the inferior yielder pays. It is possible to cull without losing milk at all if the foodstuff virtually wasted on the poor yielder is distributed among the better yielders, and—an important proviso in war-time—if rations of concentrates are provided on a basis of milk produced and not on a basis of numbers of cows. Even in war-time, a scheme for the control and treatment of mastitis, associated with a culling policy for getting rid of incurable chronic cases, would be greatly beneficial to the national milk supply.

The fall in milk-yield that was evident in the winter of 1940–41 was probably as much the result of climatic conditions highly adverse to milk production as to local shortages of feeding stuffs. The uncertain climatic factor renders any prediction as to the probable total milk yield during the mid-winter months of 1941–42 very hazardous. The yield in the winter of 1940–41 was some 7 per cent below that of 1939–40, which was itself only about 2 per cent below that of the winter of 1938–39, a winter of record output. Will this fall become greater in the most critical months of 1941–42? There are good reasons for hoping that it may not. Under next winter's rationing scheme, with absolute priority for the dairy cow in supplies of concentrates, and with the strenuous efforts that many dairy farmers have been making during the past twelve months to make their farms more nearly self-supporting as regards feeding stuffs for milk production and not merely for maintenance, the dairy cow should be adequately, though not generously, provided for during the forthcoming winter. Though culling of poor yielders is being officially encouraged, the national herd has not diminished. The hay crop, on which much depends, has been on the whole a fair one, with hay of good quality. Grass has been plentiful in most parts of the country, which means that the reserves of feeding stuffs for summer use have not as yet been consumed. The loss of milling by-products resulting from the increased rate of extraction of flour from wheat should be more than offset by the increased production of oats and mixed corn during the present harvest.

The labour situation is unlikely to become more

serious, as experienced male agricultural workers are not being called up, and more Women's Land Army recruits are being trained for work on dairy farms. The present very high prices paid for dairy cows indicates that even if certain farmers are turning over from milk production to other less-exacting types of farming that appear to be giving, for the present at least, equally good returns, their dairy animals will not be lost from the national herd. What is less certain is whether the slight trend towards summer milk production shown during the past twelve months will be accentuated. If autumn calvings are markedly fewer in 1941 than in 1940, then there will be an increased shortage of liquid milk during the critical mid-winter months. If they are not, the winter milk yield of 1940–41 is very likely to be maintained during the forthcoming winter.

THE "HOROLOGIUM OSCILLATORIUM" OF CHRISTIAN HUYGENS

By A. E. Bell

St. Marylebone Grammar School, London

THREE great works laid the foundation of modern mechanics: Galilei's "Discourses on Two New Sciences" (1638), Huygens's "Horologium Oscillatorium" (1673), and Newton's "Philosophiæ Naturalis Principia Mathematica" (1687). Of these, the second is certainly the least well known, and least accessible to the English reader[1]. Yet it is more rigorous in the treatment of its subject-matter, more strictly mathematical in style than the others, and it certainly deserves more recognition than has ever been conceded to it. From Huygens's original intention to publish a work on the construction and scientific principles of his pendulum clock (employing a cycloidal pendulum), the work grew and grew over a period of about fifteen years, and finally issued forth in 1673 with much accumulated around its central theme. Unlike most of Huygens's other writings, the work is singularly free from all Cartesian influences. Huygens himself hoped that it would be in direct line with the great work of Galilei, and his hopes were not disappointed. Newton wrote to Oldenburg, the indefatigable secretary of the Royal Society, of his "great satisfaction" with the work, and said he found it "full of very subtile and usefull speculations very worthy of ye Author". Newton especially admired Huygens's mathematical style, and considered him "the most elegant writer of modern times".

Part 1 of the "Horologium Oscillatorium", "Containing a Description of the Clock", describes in detail how the various wheels and pinions of the mechanism are put together. The description is of great interest to the student of the history of clocks because in all except one particular Huygens's clock was based on the old balance clocks dating back to the thirteenth century. This particular was, of course, the pendulum, the adaptation of which (setting aside the slight claims of Galilei) was first successfully worked out in 1656; with small differences the pendulum was used in the same way in 1673, except that Huygens had in the interval discovered (1658–59) that the cycloid is the tautochrone and that consequently a cycloidal pendulum is isochronous for arcs of all magnitudes. To make the pendulum bob execute the correct curve the flexible part of the suspension hung between metal plates or 'cheeks', themselves later found to require the cycloidal form (see below). Huygens owed much indirectly to Pascal and Wren for his discovery of the tautochrone. "I am sure that geometers will value this refinement infinitely more than all the rest of my mechanical inventions", he wrote of the cycloidal pendulum. About the same time as he made this discovery, he started on theoretical researches which led to the first general solution of the problem of determining the centre of oscillation of a compound pendulum. In Part 1 the only reference to this, however, is a purely practical one: the clock could be adjusted to measure the mean solar day by moving a rider on the pendulum rod on either side of its middle position.

Huygens hoped much from the use of his pendulum clock, suitably suspended, to determine longitudes at sea. The matter is discussed optimistically in Part 1, but no dependable results were ever obtained with regularity on the various trials carried out during his lifetime. Bifilar pendulums and many others all proved unsuitable. Huygens invented a spiral spring regulator in 1665, and brought out a clock employing this ten years later. Clearly, it was only the lack of the necessary workmanship which stood between this principle and a successful chronometer. The spiral spring regulator does not enter the pages of the "Horologium", however, and this is accordingly a digression. Huygens, in fact, put his faith in the cycloidal pendulum clock equipped with a *remontoire* for greater exactness. Such clocks he con-

sidered were shown to be extremely accurate by his discovery that when two of them were in any sort of mechanical contact their pendulums (through a principle of resonance) beat perpetually together. The astronomers were impressed, and took up the clocks, but not the mariners. Hooke was a great opponent. "Sea-men knew their way already to any *Port* . . ." he naively remarked.

Part 2 of the "Horologium Oscillatorium" is entitled "On the Fall of Heavy Bodies and their Oscillation in a Cycloid". It begins with a résumé of the law of constant acceleration under gravity, and the treatment of forces as vector quantities. Among the well-known deductions obtained by Galilei and restated by Huygens, the latter gave the statement that the speed acquired during free fall from a given height will, under suitable conditions, enable a body to re-ascend to the same height (Prop. 4). Propositions dealing with descent over one or more inclined planes then follow. There is nothing here to add to Galilei's conclusions: the latter's work is merely systematized (Props. 5 to 9). In such an oscillation as that mentioned in Proposition 4, Huygens showed that the speed of a body is unique for any given height —a conclusion which in effect he traced to the change in potential energy (Prop. 10).

A good deal of arid geometry lies at this stage between the reader and the conclusion of the work. The extension of Galilei's work to cover descent over curves, combined with Cavalieri's method of exhaustions in the quadrature of these curves is of considerable historical interest, however. The work is too intricate to explain without a series of diagrams, but the principles may be indicated. Huygens first obtained limits to the length of a circular arc less than a semicircle in terms of tangential elements (Prop. 20). By reference to the generating circle this enabled him to evaluate the length of a cycloid arc in a similar manner, and to set limits to the time of descent over such an arc as compared with the time of descent over a tangent of equal vertical height and drawn to the highest point on the curve (Props. 23 and 24). By making use of the fact that a tangent to a cycloid is parallel to a corresponding chord on the generating circle (Prop. 15), Huygens was able to relate the time of descent over any cycloid arc to the lowest point with the time of descent over a chord of the circle (Prop. 25). Thus, his proof rested for its final step on Galilei's work.

Huygens did not include in the "Horologium" his proof that in a cycloidal pendulum the restoring force is proportional to the arc of displacement. This, however, was proved in 1673 or 1674, and it shows that Huygens was certainly the first to consider the theory of simple harmonic motion. The proof can in any event be obtained easily from his propositions, but it must be admitted that these are alien, in their original, severely geometrical, form, to the consideration of forces and physical conditions.

Part 3 of the "Horologium", "On the Evolution and Measurement of Curves", appears now scarcely appropriate in a physical treatise, since it deals exclusively with problems of pure mathematics. Huygens explained that he was so intrigued with the method of evolution of the cycloid that he could not resist the temptation to investigate the evolutes of other curves. As is well known, this work was completely original. Its somewhat unusual character may be traced to Huygens's habits of experiment: the idea of an evolute would occur to him when wrapping the thread along the cycloid 'cheeks' of his pendulum. Huygens showed that the evolute of a cycloid is another cycloid, and thus established a proof for the form of the metallic plates employed in the clock (Props. 5 and 6). In Proposition 7 he showed that the cycloid is four times the diameter of the generating circle.

Part 4 of the "Horologium" must be reckoned the most important, for this contained Huygens's treatment of the centre of oscillation of a compound pendulum—the first dynamical system ever studied. This problem was too complex for Galilei, and Descartes failed to do any more with "Mersenne's problem" than to give solutions for one or two special cases—and these were erroneous. Descartes imagined that the problem could be reduced intuitively to that of determining the centre of gravity of some related solid or plane. Not surprisingly, he did not give proofs for his 'solutions'.

Huygens's work, as published, gives few clues to the order of his discoveries. By 1664, however, it is clear that he knew the general formula for the length of the equivalent simple pendulum $x = \dfrac{I}{M\,b}$ where I is the rotational moment of inertia, M the mass, and b the distance of the centre of gravity from the axis of oscillation. Huygens began with a problem bequeathed by Galilei: to find the period of a pendulum consisting of two weights at different positions along the same thread. Huygens solved this by applying the results of his study of impact and assuming that the centre of percussion is identical with the centre of oscillation. In the course of this preliminary essay he made important use of the conception of work done or of potential energy. In the "Horologium Oscillatorium", this treatment of the linear compound pendulum is simplified by supposing the separate weights of the linear pendulum to be freed at some point in the swing; the heights to which the weights could then ascend

are calculated from their speeds. Huygens's argument then is that the work done in raising each of the weights through its own height is, in the sum, equal to the work done if the sum of the weights is raised through the distance of elevation of the centre of gravity. The fundamental principle that the centre of gravity of a number of masses cannot ascend of itself through any motion of the masses under gravity was used extensively by Huygens. It followed from this that the separate masses might have their centres of gravity brought to the height of the common centre of gravity "without the expenditure of any other force besides that which resides in the system".

This direct method of attacking the problem of the centre of oscillation was not suited to the study of plane and solid figures in general, however. Huygens's account of this part of his work is very involved, and the simplest statement that can be made about it is that he was in effect applying the general formula quoted above without having a general method of computing moments of inertia. In dealing with plane figures oscillating in a plane perpendicular to their own, he adopted a geometrical "method of the wedge" to evaluate $\int v.da$ where v is the velocity of any element δa as it passes through the mid-point of its oscillation. If one imagines perpendicular ordinates erected on every element of area, each ordinate representing v for that element, a solid figure, wedge-shaped and tapering to the axis, is constructed on the plane figure as base. The treatment of the problem rested on the identity of the centres of percussion and oscillation mentioned above. Huygens's plane figures were all symmetrical about a plane perpendicular to the axis, and containing the centre of gravity. In the course of his work Huygens made use of the equation on moments of inertia:

$$I_z = I_x + I_y;$$

and he was one of the first to do so. Proposition 12 demonstrates that the moment of inertia, I, is given by Σmr^2 and that this is constant for a given axis of rotation.

The culminating point of the "Horologium" is the determination of the centre of oscillation of a suspended sphere. Combining this with the result for a uniform rod, Huygens obtained the approximate radius of gyration for a clock pendulum, and worked out the equation for the effect of placing a small mass on the rod in the manner of a rider. The clock pendulum was in practice a compromise. A flexible ribbon at the top of the rod enabled the pendulum to follow a cycloidal curve for a small arc. It was assumed that the centre of oscillation travelled in this curve.

Scarcely remembered nowadays is Huygens's proposal (Prop. 25) to base a universal measure of length on the pendulum. The *pes horarium* was to be a third part of the distance from the axis to the centre of oscillation of the bob of a simple pendulum beating seconds. The size of the bob would, of course, be immaterial provided that the centre of oscillation was known. There is, however, in the "Horologium Oscillatorium" no indication that Huygens reckoned with the variation of the length of the seconds pendulum with latitude. At the date of publication Huygens was presumably uncertain about the conclusion to be drawn from the observations of Picard at Cayenne (1671–72). This expedition first brought back evidence on the shape of the earth. "The thing would certainly be very important and constitute a remarkable property of our pendulums . . ." wrote Huygens[2]. Hooke was quicker in perceiving the bearing of the observations on Huygens's proposals: the variation of the earth's gravitational field with latitude quite nullified the idea he emphatically stated.

This part of the "Horologium Oscillatorium" curiously enough, ended with an account of a method for determining g—a method which is greatly inferior to the use of a pendulum. In this a pendulum of known period is released simultaneously with a falling weight attached to a long strip of paper. The pendulum bob, blackened with soot, makes a mark on the paper strip after swinging through one half of its arc. This gives the distance fallen and the time interval taken. Huygens's result came out at $g = 30$ ft. 2 in. per sec. per sec. where 1 ft. = 1 *pes horarium.*

The fifth and last part of the "Horologium" is famous for the statement of thirteen theorems on centrifugal force. These, as is well known, influenced Newton, who, rather disappointed that he had not pursued his own work to the same conclusion, remarked: "What Mr. Huygens has published since about centrifugal force I suppose he had before me." The first five theorems in effect state the equation $F = \frac{mv^2}{r}$, and the last eight deal with the conical pendulum. A form of this pendulum is described in Part 5.

Huygens constructed clocks employing conical pendulums in 1659 and 1667, the latter when he had more fully investigated the laws of motion involved. Controverting Hooke's claims to the invention, he pointed out, what Hooke certainly did not know, that the conical pendulum should be so designed that all revolutions of the bob describe horizontal circles in the surface of a parabolic conoid with the axis vertical. Only then would all revolutions be isochronous.

The great contributions of the "Horologium Oscillatorium" may be summarized as the introduction of work and energy considerations in the solution of the problem of the centre of oscillation, the proof that the cycloid is the tautochrone, the study of evolutes and the theorems on centrifugal force. One might go so far as to say that Huygens recognized implicitly all the laws which Newton made explicit in dynamics: the work on centrifugal force required a grasp of the second law, the compound pendulum illustrated the third law applied in a difficult example. Not until the time of D'Alembert, remarked Whewell[3], was the representation of the laws of motion in their most general form fully achieved. Huygens, Mariotte, the brothers Bernoulli, de l'Hôpital and Brook Taylor all took a part in the history of this advance, but of them all Huygens made the greatest inductive contribution.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

By DR. F. R. MOULTON, Permanent Secretary

DURHAM (NEW HAMPSHIRE) MEETING

SINCE 1931 the American Association for the Advancement of Science has held two meetings each year, the annual meeting during the Christmas holiday week and a summer meeting, usually in June. The large annual meetings are held in cities able to provide accommodation for several thousand men of science and about sixty rooms for holding scientific sessions. The summer meetings are usually held in smaller cities offering exceptional attractions. In June 1938, the Association met in Ottawa, Canada. This year it held its meeting in Durham, New Hampshire, during June 23–27, in connexion with the celebration of the seventy-fifth anniversary of the founding of the University of New Hampshire. It will strike British readers as curious that the seventy-fifth anniversary of the founding of a university should be the occasion for a celebration. However, in September the Association will participate in the symposia organized by the University of Chicago in celebration of its fiftieth anniversary.

In certain respects the Durham meeting resembled some of the meetings of the British Association. It was held at a university in a small town surrounded by a delightful countryside. The sea was near by in one direction, and lakes and mountains in the other. Summer was at its loveliest and the vacation period was at hand. There was an air of leisureliness that is unusual in American meetings. There was music, and there were social functions and many tours and excursions.

Stated statistically, about a thousand persons attended the meeting and fifty-one sessions were held at which two addresses were delivered and two hundred and ten papers were presented. In addition, there were several round-table discussions, eleven special luncheons and dinners at most of which addresses were delivered, five demonstrations and exhibits, and thirty-four tours and excursions for scientific purposes. Several of these excursions were continued well beyond the period of the meeting. In fact, the botanists continued their excursion through the State of Maine for a week after the meeting closed.

For several years the section on social and economic sciences has taken for the general theme of its programmes for the summer meetings the racial origins and social and economic patterns of the various peoples of the regions in which the meetings are held. Since New Hampshire is one of the New England States, the present inhabitants of New England were the subject of the programme of the section. The Pilgrims landed at Plymouth Rock in 1620 and for nearly two hundred years most of the immigrants to this region came from England. During this interval an orderly, cultured and somewhat aristocratic society developed. Then, with the rapid development of manufacturing and because of difficult conditions in Europe, wave after wave of new immigrants poured into New England—the Irish, the Italians, the French-Canadians and smaller percentages from every country from the Atlantic Ocean to the Ural Mountains. Twenty-seven papers were devoted to discussions of the human, religious, political, social and economic problems that were raised by these mass transfers of populations, and by the sudden and complete change in their occupations and living conditions.

Perhaps the most thoroughly organized and

completely carried out programme was the symposium by the entomological societies on "Laboratory Procedures in Studies of the Chemical Control of Insects". The programme, which was presented at four sessions extending through two days, consisted of eleven principal topics which were formally discussed by invited leaders and informally discussed by other experts in the respective fields. It is expected that the Association will publish this symposium in the near future.

It would be erroneous and futile to pretend that the men of science who were gathered at Durham thought only of the niceties of mathematical theories, of the meteorology of New England, of the complex origin and formation of its mountains, of its fauna and flora, of the qualities and functioning of the human mind, of the complexities of society, of the progress in the medical sciences, and in agriculture and forestry. All these were considered, and although they were considered seriously they only caught the conscious attention and held it temporarily. Deep reverberations of a new *Blitzkrieg* were coming out of Russia, "nearer, clearer, deadlier than before!" Civilization was, and is, making history around a sharp curve, and freedom was, and is, being defended principally by the gallant people of one small island. In the presence of such a tide in the affairs of men the attention could not long be held fixed exclusively by the wavelets of small additions to scientific knowledge.

Yet science gives a perspective that is unique. It deals with great distances, long periods of time, tremendous forces. It sees in outline the evolution of life from amœba to man. Against the background of the struggle of all life for existence it looks on the tragic vicissitudes of human history. It finds in the lower animals the elementary characters that in more complex combinations determine the nature of man. It gathers wisdom from all the history of the world instead of from only its last illegible page. It has no early millennium to offer, but it can point out certain pathways that should be avoided and others that are promising. And this men of science of the American Association, as well as those of the British Association, regard as one of their responsibilities to society.

OBITUARIES

Prof. J. C. Philip, O.B.E., F.R.S.

JAMES CHARLES PHILIP, born at Fordoun, Kincardineshire, on February 12, 1873, was both a son and nephew of the manse. He went to Aberdeen Grammar School and afterwards to the University, where in 1895 he was Murray scholar. He was a pupil of Japp and probably went to Göttingen on the latter's suggestion to become acquainted with the new science of physical chemistry as taught by Nernst.

In 1897 he came to work under H. E. Armstrong at the Central Technical College in South Kensington. Armstrong, though very critical of the doctrines of Ostwald and Nernst, was anxious to know of them at first hand. Less than a year later he was able to place Philip at Cambridge with Heycock and Neville, then engaged on their classic work on the constitution of binary alloys, in the interpretation of which the phase rule was to prove so helpful.

Philip stayed at Cambridge for a while but seized the first opportunity to return to London to the Royal College of Science as demonstrator and lecturer in January 1900. Here he remained all his life, becoming assistant professor in 1909 and first professor of physical chemistry in 1913. This was one of the earliest chairs in this subject in Great Britain. When Prof. H. B. Baker retired in 1932 he was made director of the Laboratories of Inorganic and Physical Chemistry. He took part in the design of the new laboratories in Imperial Institute Road begun in 1906 and busied himself more and more in every form of college activity—both official and social. He served for six years, 1932–38, on the Senate of the University, and was dean of the Faculty of Science in 1934 and deputy vice-chancellor during 1937–38.

Besides his teaching, Philip was actively engaged in research largely in collaboration with a continuous succession of students. His investigations ranged over a wide field: the properties of non-aqueous solutions (especially of electrolytes in organic solvents); adsorption of dissolved substances and vapours on charcoal; determination of the dielectric constant of liquids; molecular refraction; freezing-point diagrams of binary systems; chemical fogs.

It is particularly to his credit that he left behind him a strong school of younger men who to-day make the Imperial College a prominent centre of physical chemical training and research. It was characteristic of him to encourage his younger men to follow their own varied bents, and he shared his research students among them.

He became a fellow of the Royal Society in 1921. An honour which pleased him greatly was the honorary degree of LL.D. from his old University, Aberdeen, conferred on him in July of this year.

During the War of 1914–18 he was secretary of the Royal Society War Committee and largely concerned with organizing the preparation of local anæsthetics in university laboratories. In recognition of this work he was awarded the O.B.E.

Philip threw himself wholeheartedly into the activities and organization of his profession. He was secretary of the Chemical Society during 1913–24, and held the very onerous position of chairman of the Bureau of Chemical Abstracts during 1923–32, in the formation of which he took a leading part. From 1939 until 1941 he was president of the Society of Chemical Industry, having been persuaded to occupy the office for a second year. He had taken office as president of the Chemical Society only a few months before his death. He added to his labours in 1938 by consenting to prepare a history of the Chemical Society appropriate to the celebration of its centenary. Both the Science Masters' Association (1929) and Section B of the British Association (1936) had claimed him as president.

Philip's record is one of unselfish and continuous work for others, for those causes which he judged worthy. He was a devoted and active Presbyterian and gave much time to the duties of his church. He taught and carried out researches and organized with all his ability and was happy in all he did. Of such a man Meredith says:

"You of any well that springs
May unfold the heaven of things,
Have it homely and within
And thereof its likeness win."

Perhaps Philip's greatest memorial is in the memory and affection of the students of South Kensington. He sought to know every student individually, played tennis with them, sang songs at their concerts and entertained them at his house while he inducted them into the tradition of the Imperial College. At one time or another he took an active part in the management of practically all the student activities. One could never say of him, in Milton's words:

"Above the rest
in shape and gesture, proudly eminent."

This devotion to the duty which lay at hand, coupled in earlier days with a reticence of manner, made it seem as if he matured late in life—the Philip of the last decade, secure in the highest positions of his profession, was found to have a charm and a sincerity and to possess powers of leadership which we all valued. He was never forceful or aggressive; such traits were alien to his character.

The story of what he did for the College is too long to relate here in detail—rather would we express it as in "Pilgrim's Progress":

"This place has been our second stage:
Here we have heard and seen
Those good things that, from age to age,
To others hid have been."

Philip retired from his professorship under the age limit rule in 1938. He was given many tangible expressions of loyalty and admiration, not least by the many old students whose careers he followed and who looked to him as a friend. The recall to duty followed almost immediately: he was summoned to act as deputy rector while Sir Henry Tizard was engaged on other work. When war came this position was both arduous and exacting, the more so as the College decided to remain in London and carry on its work. Philip slept there most nights and was always to be found at his post.

His devotion to duty made him take on other, equally strenuous duties at this stage, in connexion with the allocation of scientific and technical personnel to posts in the Services and in war industries.

He became chairman of Committees of the Royal Society and of the Ministry of Labour and National Service concerned with the institution and operation of the Central Register; he also accepted the chairmanship of the University of London Joint Recruiting Board. It is said that this last position involved his interviewing about six thousand young men for an average of fifteen minutes each during the last two years. To all these offices he brought soundness of judgment, endless patience and a firm determination that everyone should have a fair deal.

Too many tasks were piled on his broad and willing shoulders, and there is little wonder that his strength eventually failed. He was taken in the very height of his achievement, rich in all the honours of his profession, richer in the love of his friends. Perhaps it is better so, than to live on the "other side of the hill" as Walter Scott called it and see one's powers, physical and mental, growing less.

Philip's teaching and the example of his personal life was to emphasize the significance of those non-material values commonly termed moral and spiritual. As he said, "surely the finest things in human life are the most difficult to express or define".

Philip married Jane Henderson of Aberdeen and had a son and a daughter: such is the bald statement, but it conceals a bountiful married life; he would have achieved far less without the constant help and support of Mrs. Philip. And their philosophy:

"I am content with what I have
Little be it, or much."

E. F. ARMSTRONG.

We regret to announce the following deaths:

Prof. Victor Jellos, formerly of the Kaiser Wilhelm Institut für Biologie, Berlin–Dahlem, known for his work on heredity and genetics, on July 5, aged fifty-three years.

Prof. E. Kremers, emeritus professor of pharmaceutical chemistry in the school of Pharmacy, University of Wisconsin, on July 9, aged seventy-six.

Prof. E. E. Maar, professor of the history of medicine in the University of Copenhagen, aged sixty-eight.

Prof. Paul Sabatier, For. Mem. R.S., professor of chemistry in the University of Toulouse, who was awarded the Nobel Prize for Chemistry in 1912, aged eighty-six.

Eng.-Capt. J. Fraser Shaw, chief engineer of the Fuel Research Station, Department of Scientific and Industrial Research.

Mr. W. A. Taylor, O.B.E., formerly a superintending examiner at the Patent Office, on August 18.

NEWS AND VIEWS

The British Association

A MEETING of the Division for the Social and International Relations of Science of the British Association will be held, circumstances permitting, during September 26–28, beginning on Friday morning, September 26, at the Royal Institution, Albemarle Street, London, W.1. The general subject of discussion will be "Science and World Order". At successive sessions, speakers representing science in Britain, the Empire and other countries will deal with the following topics (The international aspects will be stressed throughout): September 26, "Science in Government" (morning), "Science and Human Needs" (afternoon); September 27, "Science and World Planning" (morning), "Science and Technological Advance" (afternoon); September 28, "Science and Post-War Relief" (morning), "Science and the World Mind" (afternoon).

At the conclusion of the meeting, the President, Sir Richard Gregory, will announce a charter of scientific fellowship, which has been drawn up by a Committee of the Division and adopted by the Council of the Association. Tickets of admission (without charge), accompanied by full particulars, will be forwarded up to the limit of accommodation available, to those who intimate their wish to attend, to the Secretary, British Association, Burlington House, London, W.1. Intimation should not be given by telephone. Applicants should state whether tickets are desired for all three days, or for any particular day or days. Applications should be made as early as possible, and in no event later than September 22.

German Crimes at Lwow

NEWS has just been received in London of the death, in deplorable circumstances, of Prof. Casimir Bartel, formerly rector and professor of geometry in Lwow Technical College and prime minister of Poland in 1926, 1929 and 1930. He was fifty-nine years of age. According to *The Times* of August 27, Prof. Bartel was shot by the Germans for conspiring with the Soviet authorities during the Russian occupation of Lwow. It is, however, known that Prof. Bartel refused to collaborate politically with the Russians, but did agree to co-operate solely in scientific and humanitarian matters. It was hoped that Prof. Bartel would leave Lwow after the outbreak of war between Russia and Germany, and become chairman of a committee in Russia to deal with Polish welfare problems, but he wished to remain at his college, where he was arrested a month ago. About sixty professors of the University and the Technical College at Lwow were arrested. They included Prof. S. Pilat, professor of petroleum technology, Prof. R. Rencki, professor of internal diseases, Prof. W. Sieradzki, professor of forensic medicine, and Prof. T. Ostrowski, professor of surgery. Their fate is unknown. Thus have the Germans repeated the same persecution of men of science and learning at Lwow which they carried out at Cracow, when a hundred and fifty university professors were sent to the concentration camp at Oranienberg.

State Bursaries in Science

IN order to meet the demands of the Services and of industry for technical officers, the Board of Education has established a scheme of State bursaries tenable at universities and at certain technical colleges. The demand is particularly pressing for men and women for radio work for which physics is essential; others will be required for posts needing qualifications in engineering and in chemistry. The bursaries will cover fees and maintenance allowances to meet the full cost of residence at the university or college at which the awards are held. The qualifying standard will be a pass in physics, chemistry, or mathematics in certain combinations in the higher certificate examinations. Applications are being accepted also from boys and girls who have passed the London Intermediate Science examination in the appropriate subjects.

Applications cannot as a rule be entertained from pupils who left school before the end of last term and are now in employment, nor will students at present attending universities and university colleges be considered eligible. The minimum age is eighteen years, unless the applicant possesses exceptional qualifications. It is expected that some of the holders of State bursaries may be able to qualify for a university degree before they are required for national service; others will have to relinquish their university course at the end of a year's training. The Board has promised that in suitable cases these will be considered after the War for such assistance as may be necessary to enable them to complete a degree course. Further information can be obtained from the Board of Education, Branksome Dene Hotel, Bournemouth.

University of London

On August 25 the headquarters of the University of London administrative staff will remove from Royal Holloway College, Englefield Green, Surrey, to Richmond College, Richmond, Surrey (telephone, Richmond 2301). The Matriculation and School Examinations Department of the University will remain at Highfield, Englefield Green, until the middle of September, when it also will remove to Richmond College.

The title of professor emeritus of physiology in the University has been conferred on Prof. Winifred C. Cullis on her retirement from the Sophia Jex-Blake chair of physiology at the London (R.F.H.) School of Medicine for Women.

Miss Esther M. Killick has been appointed to succeed Prof. Cullis. She has been since 1939 lecturer in industrial physiology at the London School of Hygiene and Tropical Medicine.

University of Poznan

According to Science Service, the former Polish University of Poznan, which has now become the University of Posen, reopened this summer under German direction and for German students. The city of Poznan is in the western part of Poland, which has been set aside for permanent and total German occupation; Posen is the German spelling of its name. Its university is one of the newest in Europe, having been founded in 1919. Before the outbreak of present hostilities, it had a student body of something more than five thousand.

A New British Scientific Journal

Imperial Chemical Industries propose to publish a new quarterly journal of science, and it is hoped that the first number will appear during the autumn of this year. The journal will be translated into at least three foreign languages and will circulate in all parts of the civilized world. Though published by Imperial Chemical Industries, it will in no sense be an advertising medium, but, by laying principal emphasis upon British contributions to science, will form part of the national war effort and as such has the approval of His Majesty's Government. Many distinguished men of science have already expressed their willingness to contribute to its pages, and the chief article of the inaugural number will be by the Astronomer Royal, Dr. H. Spencer Jones. Such a journal, especially in its translated forms, will undoubtedly contribute largely to the national war effort and we wish it every success.

First American High School of Science

The first "graduating exercises" of the New York High School of Science were held on June 26, with the commencement address delivered by Dr. Irving Langmuir. Diplomas were presented to the pioneer class of 130 boys. Every one of the graduates has signified his intention of pursuing further studies in science, leading to careers in research, engineering and medicine. The new high school was organized in 1938, with curriculum and faculty built around the idea of making science the central theme in education. Not only were science courses made the pivotal subject studied, but also such subjects as English, foreign languages, the social sciences, etc. were presented with primary reference to their relation to the natural sciences.

New York was combed for boys with special interest in, and aptitude for, science. Out of five thousand applicants, a student body of two thousand was selected. A rigorous entrance examination was held. The new school was opened in a building of the conventional school type, so that many changes had to be made, especially in the installation of additional laboratories, to adapt it to its new purpose. In addition, there is a visual instruction lecture room, a large library, an English workshop, a voice-recording studio, four mechanical drafting-rooms, a graphic arts shop, a music room, a gymnasium and a swimming-pool.

John Innes Horticultural Institution

The report of the Director of the John Innes Horticultural Institution for the year 1940 has just been issued. The War has affected all the departments, the reduction in personnel by war service and the replacement of research work by the growing of vegetables and drug crops and seed production have dislocated some of the activities. Nevertheless, the results obtained from experiments on incompatibility, parthenocarpy, production of polyploidy in plums, cherries and pears, heterosis, polygenetics and linkage, provide useful and important data. The cytological department has found that cold treatment, colchicine and starving the nucleus of nucleic acid are excellent methods for analysing the behaviour of chromosomes during division. The preparation of a list of chromosome numbers of more than a thousand tropical species will be of great value to future workers. The identification of several plant pigments has been made by the Biochemistry Department. It has been found that both the ivory and yellow forms of *Antirrhinum majus* contain apigenin, and that the yellow pigment probably is chalkone. The yellow pigment in *Papaver radicatum* is gossypetin.

A useful innovation is the publication of pamphlets —John Innes Leaflets—which explain in simple terms the lessons learnt from the experiments on composting, soil sterilization, incompatibility, sterility and time of flowering in fruit trees. Already ten thousand of the leaflets have been sold. These pamphlets, together with more than fifty scientific papers published during 1940, indicate that very creditable work has been done under adverse conditions.

Malaria in India

In a paper in the July issue of the *Asiatic Review*, Sir Alfred Chatterton states that the organization employed at the present time in anti-malarial work in India, where many millions of cases occur every year, are the Malaria Institute of India, the Indian branch of the Ross Institute, the malarial sections maintained by some of the provincial health departments, the medical departments of certain railways and a few voluntary associations, such as the Assam Medical Research Society and the Central Co-operative Anti-Malarial Society of Bengal. The Malaria Institute of India is the main centre for research and for the training of medical officers from all parts of India in anti-malarial work. By offering advice to Provincial Governments it plays an important part in co-ordinating work throughout the country. The

Indian branch of the Ross Institute, started in 1930, is mainly concerned with the control of malaria in the tea and coffee estates, rubber plantations, mines, sugar factories, cotton and jute mills and other industries in various parts of India. The chief function of the Central Co-operative Society of Bengal is propaganda, in which it has been very successful as it has 2.362 rural societies under its control. These various organizations co-operate freely both in general conferences and in joint inquiries and investigations.

Empty Space

Dr. Robert G. Aitken brings together some interesting information on this topic in Leaflet No. 148 issued by the Astronomical Society of the Pacific. The diameter of the universe made accessible by the 100-inch telescope is about 600 million light-years, and the 200-inch telescope will double the diameter of this sphere. In this smaller sphere there are 100 million stellar systems with an average content of 10^{10} stars, the diameters of which average about twice that of our sun. The stars fill about 10^{-26} part of space and it is believed that the space between the separate stellar systems—extragalactic space—is absolutely empty. In interstellar space, however, in which the stars are distributed at average distances of five or six light-years, electrons, protons, atoms, gas molecules, minute dust particles and also larger pieces of matter, ranging up to the size of meteorites, are known to exist.

There is so much space that the mass of this interstellar matter may be two or three times the combined mass of all the stars, and, with the exception of the larger pieces of matter, the interstellar particles produce a number of problems for the astronomer because of their effect in absorbing and scattering light. The light from the more distant stars passes through space laden with gas molecules, and the intensity of the stellar lines will increase with increasing distance—a fact which has been utilized in recent times to estimate the distances of these stars. Previous conclusions regarding the distances of the fainter stars based on the inverse square relationship must now be modified, and these distances may not be so great as astronomers believed a few years ago. Another important point is the greater absorbing and scattering effect upon the shorter violet rays, and in consequence myriads of stars cannot be photographed by the use of ordinary photographic plates. Many thousands of stars, the existence of which had been previously unsuspected, have recently been photographed with new red-sensitive plates—convincing evidence of the presence of interstellar matter. An enormous field for research in this direction lies before the astronomer.

Two Notable French Men of Science

On August 21 and 22 respectively occurred the centenary of the death of one distinguished Frenchman and the bicentenary of the birth of another. The first of these men is the eminent geologist and civil engineer Jean François d'Aubuisson de Voisins, who was born in the South of France on April 16, 1769, and died at the age of seventy-two on August 21, 1841. For four years D'Aubuisson was a student under Werner at the Mining School at Freiburg, and it was while in Germany that he studied the basalts of Saxony, an essay on which he published in Paris in 1803. This essay, in which the Wernerian doctrines were adopted, was reported on by Haüy and Ramond, who advised the author to inspect the basalts of Auvergne. This D'Aubuisson immediately did, with the result that in a paper "Sur les volcans et les basaltes de l'Auvergne", read to the French Institute in 1804, he abandoned many of the views he had hitherto held. "The facts which I saw", he wrote, "spoke too plainly to be mistaken; the truth revealed itself too clearly before my eyes, so that I must either have absolutely refused the testimony of my senses in not seeing the truth, or that of my conscience in not straightway making it known." D'Aubuisson's most important work was his "Traité de Géognosie", published in 1819, but he was also known for his investigation in hydraulics (1826–30) and his "Traité d'Hydraulique, à l'usage des Ingénieurs", an enlarged edition of which, published in 1840, was translated into English by Bennett and published at Boston, Massachusetts, in 1852.

The other Frenchman to whom we refer is the naval officer and navigator Jean-François Galaup de La Pérouse, who met a tragic fate following in the footsteps of Cook. La Pérouse was born at Albi, in the department of Tarn, August 22, 1741, and at an early age entered the French Navy. When serving in the *Formidable* under Conflans against Hawke, he was wounded and taken prisoner. During the peaceful years of 1764–78 he did all in his power to fit himself for his profession, and in the *Astrea* in 1782 showed much skill and resource in penetrating into the Hudson Bay and capturing several British posts. The reputation he gained led to his appointment to command the expedition comprising the ships *Boussole* and *Astrolabe*, which left Brest on August 1, 1785, to visit the Pacific. Crossing to South America, the ships rounded Cape Horn and from thence proceeded to California, China, the Philippines and Kamschatka. Sailing south again, La Pérouse reached Australia in the beginning of 1788 and from Botany Bay sent a letter to the French Minister of Marine giving particulars of the voyages he intended to make. From that time onwards for many years nothing was known of the fate of the ships. In 1791 Admiral d'Entrecasteaux in the *Research* and *Espérance* searched in vain for them, but some meagre information was secured by the ship *Hunter*, which, sailing from Bengal in 1813, visited Australasia. On board the *Hunter* was Peter Dillon (1785?–1847) who as captain of the *Saint Patrick* in 1826 discovered that the *Boussole* and *Astrolabe* had been wrecked off Vanikoro, north of the New Hebrides. Dillon made a second voyage in the *Research* and brought back to France many relics of the unfortunate expedition. For his services he was made a chevalier of the Legion of Honour. There is a bronze statue of La Pérouse at Albi, and his name has been given to the strait between Sakhalin and Yezo.

Edward Janeway (1841–1911)

Dr. Edward Gamaliel Janeway, a distinguished New York consulting physician, was born at New Brunswick, New Jersey, on August 31, 1841. He studied medicine at the College of Physicians and Surgeons, New York, and qualified in 1864. He spent some time after qualification at the Bellevue Hospital, New York, in the study of morbid anatomy, which formed an excellent foundation for his clinical work. In 1872 he was appointed professor of morbid anatomy and in 1881 of psychiatry and neurology at the Bellevue Hospital Medical College, where he succeeded Austin Flint in 1886 in the chair of internal medicine and held this post until 1892. From 1898, on union of the Bellevue Hospital Medical College with New York University, until 1907, he was clinical director of the amalgamated institution. In addition to general medicine he took a keen interest in public health, especially in the campaign against tuberculosis, and was for some time president of the National Association for the Study and Prevention of Tuberculosis. He died at Summit, New Jersey, on February 10, 1911. He made numerous contributions to periodical literature, but was not the author of any book. His son, Dr. Theodore Caldwell Janeway (1872–1917), professor of medicine at Johns Hopkins University, was the author of a book entitled "The Clinical Study of Blood-Pressure" (1914), which was a pioneer work on the subject.

The Night Sky in September

The moon is full on September 15 and there will be a partial eclipse, invisible at Greenwich, the middle of the eclipse occurring at 17h. 47m. U.T. Venus is an evening star and is in conjunction with the moon on 24d. 00h. Mars is a morning star, crossing the meridian at 2h. 54m. and 0h. 46m. at the beginning and end of the month respectively, and is in conjunction with the moon on September 9d. 02h. Jupiter is a morning star and crosses the meridian at 6h. 32m. and 4h. 48m. on Sept. 1 and 30; the planet is in conjunction with the moon on Sept. 13d. 18h. and will be 5° N. of the moon. Saturn is a morning star and souths at 4h. 12m. in the middle of the month. On Sept. 11d. 22m. it is in conjunction with the moon and will be 3° N. of the moon. New moon occurs on Sept. 21 and there will be a total eclipse of the sun, invisible at Greenwich. The path of totality passes along the northern end of the Caspian Sea, Turkestan, Central China, and the western part of the Pacific. The longer evenings provide an opportunity for viewing the Milky Way, the great bifurcation occurring in Cygnus and extending along the galactic equator. The eastern portion can be seen running through Aquila, Scutum, Sagittarius and Scorpio, where the broken western stream partially unites with it. In the late evening the beautiful group of stars in the constellation of Taurus—the Pleiades—can be seen. Their rising with the sun is referred to by the Greek poet, Aratos, as the harbinger of summer, and their rising at night, that is, after sunset, indicated the coming of winter. The variable star, Algol, is well placed for observation throughout the whole night and its rapid fluctuations in magnitude are always a source of interest. The pride of the Constellation of Andromeda—the Great Nebula of Andromeda—is visible to the naked eye and can be easily recognized close to the star ν Andromedæ. It looks like a 'fleecy' star, but is spiral in structure and is a great universe like our galaxy, about 870,000 light-years away, containing hundreds of millions of stars. In the outer portions are many stars of the Cepheid variable type, so valuable for the determination of distances.

Announcements

A German scientific institute has recently been opened at Madrid.

The Swiss Society for the Investigation of Nature will hold its 121st annual meeting at Basle during September 6–8.

Dr. Andrew F. Skinner has been appointed successor of Prof. W. W. McClelland in the associated posts of Bell professor of education in the University of St. Andrews and director of studies at the St. Andrews and Dundee Training Centre.

The Australian Government proposes to proceed immediately with the provision of four distilleries costing £1,250,000 for the production of power alcohol from wheat. The distilleries will be constructed in New South Wales, Victoria, Western Australia and South Australia. Each will have a capacity of three million gallons a year.

The College of Physicians of Philadelphia have awarded the Alvarenga Prize to Dr. John J. Bittner, of the Roscoe B. Jackson Memorial Laboratory, for his studies on cancer.

The Annual Congress of the Ophthalmological Society of the United Kingdom will be held in Cambridge on September 4 and 5, when Drs. O. M. Duthie and S. Zuckerman will open a discussion on ocular injuries resulting from the War. Further information can be obtained from Mr. Frank Law, 30, Devonshire Place, W.1.

The Committee of Privy Council for the Organization and Development of Agricultural Research has appointed, to fill vacancies caused by normal retirement, Major James Keith, who is the chairman of directors of the North of Scotland Bank, and owner of extensive farming areas in Norfolk and Aberdeenshire, and, after consultation with the president of the Royal Society, Prof. F. T. Brooks, professor of botany in the University of Cambridge, and Prof. D. Keilin, Quick professor of biology in the University of Cambridge, as members of the Agricultural Research Council. The Council of Privy Council has also appointed, to fill two other vacancies, Prof. J. A. Scott Watson, Sibthorpian professor of rural economy in the University of Oxford, and, after consultation with the president of the Royal Society, Prof. C. R. Harington, professor of biochemistry in the University of London.

"The Philosophy of Physical Science"

IF I return to this question, it is because I am so deeply impressed by its importance[1]. If Sir Arthur Eddington's theory is sound, its consequences are tremendous—to physics, to philosophy and to humanity. A peculiarity of the situation is that there can be no middle way; the theory must be either entirely right (apart possibly from unimportant details) or entirely wrong.

In his letter to NATURE (in which, incidentally, I do not find a single one of my objections answered) Eddington seems to me to have himself supplied proof that his theory is wrong. He agrees that the Michelson-Morley experiment disclosed one of the "brute facts" of Nature; thus we may, without logical inconsistency, imagine it having turned out otherwise than as it did. He then discusses "the situation which would arise if the experimenters have let us down badly and the true result is that which Michelson originally expected". He says this would indicate that "there is a strain depending systematically on the velocity". The essential point is that, however we interpreted the experiment, there would be a velocity disclosed by it, so that relativity would go up in smoke. There is no logical inconsistency in this, and yet, if Eddington's scientific epistemology had been sound, it would have been impossible to imagine such an event without logical inconsistency.

For we do not discuss the situation which would arise if someone were to discover the largest prime number, or two integers of which the ratio is $\sqrt{2}$, because we know, and can prove, that both events are impossible; we cannot imagine them happening without logical inconsistency. Eddington can only maintain his scientific epistemology by proving that it is equally impossible to imagine special relativity, Heisenberg's uncertainty, etc., being different from what they are. Instead of proving that certain events are unimaginable, Eddington starts imagining them.

Surely, however, the simplest and cleanest test case is not the Michelson-Morley experiment, but the finiteness of the speed of light. This is obviously very fundamental (in Eddington's sense), being an essential part of the theory of relativity, and it contains no jungles of "bogies" or "tail-chasing" in which to get lost. If we cannot discover any epistemological proof of this, Eddington's theory obviously falls. I cannot discover such a proof. Does Sir Arthur Eddington know of one?

J. H. JEANS.

[1] NATURE, 148, 140 (1941).

IT appears that scientific men are divided into two classes: the experimental type and the theoretical type. The difference would seem rather a matter of temperament than of necessity. Perhaps it would be wiser to separate them into two other classes which are rather of the same kind: those who are model makers and those who deal purely in abstract ideas and the essential relation of things.

There is no reason to place these two classes, as Prof. Stark has done, in their order of merit, and to use this order to bolster up a political creed, because it is quite clear to those who know the history of science that both types are needed in the development of physics. Both classes have their limitations, and an analysis of the subject is bound up with one's ultimate scientific philosophy.

The model makers are rather at the mercy of irrelevant analogies, which can be avoided only if essentials are related, as in the group theory, for example. The analogies, in these cases, are good servants but bad masters. Again, makers of models manufacture mistakes and difficulties. Many examples could be cited. One particular case that has come to my notice is connected with the idea of the group velocity of a set of waves. If we look at the ripples made by a stone on the surface of a pond, we often see that whereas the group of wavelets moves with one velocity, the crest of each individual wave moves with another one. A group velocity can be approximately defined which only differs from the phase velocity when this is a function of the frequency. Group velocity does not really exist, but is a close approximation in certain conditions, and becomes rather indefinite when component waves are differently attenuated.

In a definite problem, say the calculation of how a group of waves arrives at a distant point, if the problem is definitely stated, the answer can be just as definitely expressed. A difficulty is manufactured if the problem is put in the form: The group is sent out. At what time will it arrive at a distance x, say? An indefinite answer is involved because an indefinite group velocity is used in the question.

Similar examples are the quantum theory of dynamics, the mechanical theory of the ether, etc. In the former, the model of an electron rotating about a nucleus, in the same way as the earth rotates about the sun, gives rise to such questions as where the electron is at any time. This is a meaningless question, suggested by a false analogy. It is put in such a form that it implies relations that do not belong to it. It is like the question: Have you stopped beating your wife?

All observable quantities, for example, the spectra of the elements, etc., can be expressed in terms of the quantum theory in a perfectly definite manner, as in the preceding group velocity example. The questions as to the individuality of the electron, which have puzzled so many physicists, are not really relevant.

A method of procedure can be postulated by which a definite answer is given to a definite question. This is the correct theoretical basis. A freedom from the fetters of mechanics is necessary to develop many of our new theories, which are not built in the image of molar mechanics, the only ones which the model-makers can understand.

It is the theoretical side of physics which is so necessary to free us from preconceived ideas. But theory alone is not enough. It is difficult to see how the theorist could invent all the living realities which it is his business to analyse. The experimental facts must come first. Eddington seems to take rather an extreme view of this case, as if it were possible, by epistemology and epistemology alone, for the theorist to deduce all the essential relations—all the fundamental constants in relativity, quantum theory and non-Euclidian geometry—without reference to any facts. It is probably a matter of theoretical power and efficiency whether this can be achieved, but there is a tendency towards it.

Although experiment is necessary, it is encouraging to realize that a large number of experiments are very often unnecessary, inasmuch as further experiments tend to confirm the previous ones; and it is often found that an experiment on a matter which seems entirely outside the original scheme is merely the same experiment as the previous one repeated, and that if we had sufficient theoretical power, we should realize that the two experiments imply the same thing. There is a tendency, therefore, to reduce experimentation in proportion as our theoretical power increases. If we could rely on this completely, only one experiment, to find out which point the curve goes through, so to speak, would be necessary. (I have been accused of drawing curves through one point only!) All that is necessary is to fix, say, the value of the ordinate at some specified value of the abscissa.

It is encouraging to think that experimenting, although necessary at the present moment, and probably the quickest way of getting results, should become less and less necessary as our theories improve. It may be that we shall reach a final state, as implied by Eddington, in which all the constants of nature are interrelated, and can be fixed from epistemological considerations alone.

T. L. ECKERSLEY.

Weatheroak,
Danbury,
Essex.

A CORRESPONDENCE between two men of such astronomical mental calibre as Jeans and Eddington, firing long-range shots at each other, should, I suppose, be read in silence and with respect by the ordinary man in the street. It is indeed very enjoyable in these days to have such a discussion, but first of all we must thank Jeans for the very human confession that he had been "re-reading" Eddington's book. It is comforting to think it was not just our fault we did not get it all the first time.

Jeans sums up Eddington's contention in paragraph 2 by saying that "all those laws of Nature that are usually classed as fundamental, as well as the values of the constants of Nature, can be foreseen 'from epistemological considerations, so that we can have *a priori* knowledge of them' ". "*A priori*" knowledge is given, quoting Eddington again, as "knowledge which we have of the physical universe prior to actual observation of it". From this it is fair to say that Eddington claims that fundamental laws are objective, yet in his answer towards the end he states that there is no such thing as a truly objective law. Eddington should, therefore, challenge Jeans's summary of his main contention, yet he does no such thing.

I have always regretted the Michelson-Morley experiment. Things were perfectly satisfactory before their distressing negative results. I feel we are not at the end of this story, just as we are not at the end of the story that the red shift in the spectrum means receding speed, unless we tie ourselves to the Hilaire Belloc creed and "never, never let us doubt, what nobody is sure about". To say that without the Michelson-Morley experiment we should find ourselves "faced with a universe far more complicated than we have lately imagined" can only be agreed to by those who can dart with such facility from physics to metaphysics.

Finally, a protest against 'plugging' the word 'epistemological'. It is neither pronounceable nor understandable.

J. T. C. MOORE-BRABAZON.

81 Albert Hall Mansions,
S.W.7.

SIR JAMES JEANS proposes the finiteness of the velocity of light as a test case. I answer: Certainly this is *a priori* knowledge, but of a rather trivial kind. We know *a priori* that the velocity of light is not infinite, just as we know *a priori* that the velocity of light is not blue or hexagonal or totalitarian; it is not the sort of thing to which these terms could apply. The alternatives "exceedingly large" and "actually infinite" concern only the abstract quantities which are the theme of pure mathematics; this is equally true of the alternatives "exceedingly small" and "actually zero". No such alternatives exist for physical quantities defined in terms of observation. When an *observer* sets out to determine the velocity of light, an infinite result is not among the possible alternatives; and if he announces that he has found the velocity to be, not merely exceedingly large, but actually infinite, we know *a priori* that the announcement is untrue.

In so far as the existing relativity theory rests on the assumption that the velocity of light is not infinite it is safe from experimental contradiction. In regard to the aspect in which it is not so immune, Jeans's remarks seem to me mainly reiterative, since he again ignores the difference between identification by description and identification by pointing. It is a logical impossibility that the Michelson-Morley experiment should give a null result in the conditions *described*; but the possibility imagined is that a bogey, supposed to have been laid, has come to life again, so that the conditions described are not those which have been *pointed out* to the experimenter. Similarly, it might have turned out that the velocity of light did not agree with the ratio of electrical units; in that case we should have had to await the discovery of Hertzian waves before we could see how electromagnetic wave theory applied. When Dirac's "holes" were first put forward they were identified with protons; but brute facts were discordant, and the hole theory went up in smoke. That was because the hole described was not the proton pointed out. Later the positron was discovered, and it was seen how the hole theory applied.

Since these letters will be read by many who are unfamiliar with the basis of the epistemological theory, it seems desirable to explain briefly why a scheme of laws arrived at in an *a priori* way is expected to coincide with the scheme arrived at by analysis of observational knowledge. The development of fundamental physics must go on and on, either steadily

or by a succession of revolutions, until the physicist has (in his limited view) reached the bottom of things. The important question is: Will he recognize "the bottom of things" when he reaches it, and can we already say what are the criteria by which he will recognize it ? If so, we can reverse the usual order of inquiry and begin with these criteria. We can, for example, work out the properties of the "particles" which, according to these criteria, could be accepted as really elementary structural units. In that way we develop a scheme of laws relating to the concepts in terms of which phenomena are ultimately to be described, confident that the physicist, who is working his way down from the top, will come to this scheme. Any other scheme could only be a temporary resting-place from which he must be driven by the intellectual urge which started his inquiry. Whether this will succeed as a practical method—whether it is the short way round or the long way round—cannot definitely be foretold; but it is found by trial to be the short cut, unless we have been greatly deceived. If we imagine experimental results to have turned out differently, we eliminate the evidence that it is a short and (in the present state of knowledge) practicable method; but we do not impugn its validity.

In reply to Lieut.-Colonel Moore-Brabazon, I do not see how the statements (which are, I think, a fair summary of my main contention) constitute a claim that the so-called fundamental laws are objective; I concluded that they are subjective. I fully agree with Mr. Eckersley's letter.

A. S. EDDINGTON.

The Observatory,
Cambridge.

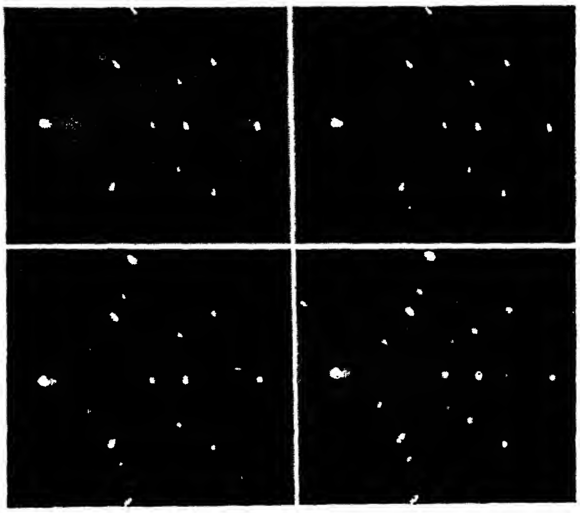
Temperature Study of the Diffuse X-Ray Diffraction by Diamonds

IN a recent letter in NATURE[1], we pointed out that all diamonds show one kind of ("primary") diffuse X-ray diffraction, associated with the ordinary {111}, {220}, {113}, etc., reflexions on Laue photographs, but that only Type I diamonds show the special ("secondary") diffraction, the characteristic appearance of which takes the form of fairly sharp streaks or triangles of spots. The suggestion was made that these two types of diffraction, though associated with each other and with the Laue reflexions, may have different origins. This is now supported by the following new experimental facts. First, in contrast to the primary diffuse spots, the *secondary* effects vary considerably in intensity even for diamonds of similar shape and size (Type I diamonds, however, always show some effect, whereas Type II show none). Secondly, it is found that, whereas this secondary diffraction is only slightly affected in intensity by a temperature change of more than 800° C., the *primary* diffraction (for diamonds of both types) is much more strongly temperature-sensitive.

The accompanying illustrations are typical of many taken using various specimens, changing crystal orientation, time of exposure, etc. Photographs (*a*) were taken with a small octahedral diamond of Type I, at 650° C. and at 30° C. respectively, under similar conditions of position and exposure time. The primary diffuse spots corresponding to (111) copper $K\alpha$ and β, and (113) copper $K\alpha$ reflexions are clearly much stronger at the higher temperature; the secondary diffuse spots (three (111) copper $K\alpha$, three (111) copper $K\beta$ and two (113) copper $K\alpha$) show definite, but less marked enhancement. It is interesting to note that the third point of the (113) "triangle" does not appear even at high temperatures.

Photographs (*b*) were taken with a very thin diamond plate, also of Type I, at 30° C. and at − 180°C. The crystal orientation was changed a little from the (*a*) position, in order to intensify the primary diffuse spot in the room temperature photograph; this, however, weakened the (113) diffuse reflexions, which are no longer reproducible. For the low-temperature photograph the specimen was completely bathed in a direct, continuous stream of liquid oxygen. In order to allow for absorption and scattering of the incident X-rays by the liquid oxygen, the exposure was increased until the Laue spot and background intensities were obviously stronger than those of the room temperature photograph. Even so, the primary diffuse spot has practically disappeared, the secondary spots being weaker than before but still quite distinct.

(*a*) 650° C. 10 min. θ = 18° (*a*) 30° C. 10 min. θ = 18°



(*b*) 30° C. 10 min. θ = 18·6° (*b*) − 180° C. 15 min. θ = 18·6°.

Similar experiments on Type II diamonds showed the same weakening of primary diffuse diffraction at low temperatures, and other photographs verified this for {220} and {113} diffuse reflexions. All these temperature changes were reversible.

Sir C. V. Raman and others[2,3] have reported a negative result for low-temperature experiments on diamond, but without the publication of photographs or of data which would indicate whether they were, in fact, observing primary or secondary diffraction.

The *primary* diffuse spots, observable and temperature-sensitive for both types of diamond, would appear to correspond closely to the diffuse spots observed for all other crystals under suitable conditions of temperature, orientation and wave-length of incident radiation. It seems obvious, however, that the *secondary* spots and streaks on photographs of Type I diamonds, however interesting in themselves, can scarcely be taken as typical of diffuse diffraction in general, since the counterpart of the triangles has not yet been observed for any other substance, while streaks are relatively uncommon. It is noteworthy that the selective Bragg reflexions

from diamonds giving strong secondary effects were relatively weak, being barely visible on a fluorescent screen; those from diamonds giving very weak or no secondary diffraction were much stronger, the (111), (220), etc., reflexions being visible on a fluorescent screen in broad daylight not only in the "characteristic" position but also throughout the entire range of Laue reflexion. This confirms the observation that strong secondary diffraction is associated with powerful extinction effects.

Determination of Sex in Scalpellum

SEXUAL conditions in the Cirripedia are very varied[1]. They comprise such species as:

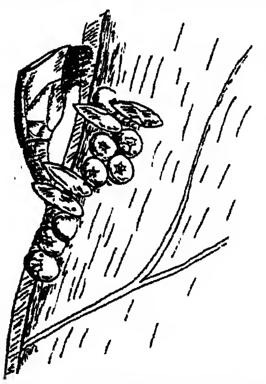
(1) Hermaphrodite forms with 'complemental' males, for example, *Scalpellum scalpellum, Ibla cumingii*;

(2) Hermaphrodites with sterile complemental larvæ, for example, Rhizocephala;

(3) Hermaphrodites only, for example, most Pedunculata (Lepas, Pollicipes, etc.), Operculata (Balanus, Coronula, etc.), Ascothoracica;

(4) Females with complemental males, for example, *Scalpellum velutinum, S. ornatum, Ibla quadrivalvis*, Acrothoracica.

The chromosomes of *Lepas anatifera*, which falls into group 3, were examined by Witschi[2]. He found the diploid number to be 26 and showed that no distinguishable sex chromosomes were present.



GROUP OF COMPLEMENTALS ATTACHED TO THE MANTLE OF A HERMAPHRODITE *Scalpellum scalpellum*, INCLUDING FOUR CYPRIS LARVÆ, NINE DWARF MALES AND ONE QUASI-HERMAPHRODITE. (× 12.)

I have examined the chromosomes of *Scalpellum scalpellum*, which falls into group 1. The diploid number of 32 was found in spermatogonia of complemental dwarf males and of hermaphrodites. No sex chromosomes can be distinguished at meiosis, the haploid number being 16.

Gruvel[3] observed oogonia in the complemental males of *S. peronii*, which also falls into group 1. I have seen the same in *S. scalpellum*. Moreover, one hermaphrodite of *S. scalpellum* which I received from Plymouth had an unusually large number of complementals. Of these four were unmetamorphosed cypris larvæ, nine were typical degenerate dwarf males, and one excluded from the male-containing pocket of the hermaphrodite, had the structure of a small hermaphrodite (see accompanying illustration).

The absence of sex chromosomes, presence of oogonia in the complemental males and this odd hermaphrodite-like complemental point to an environmental control of sex determination such as that existing in Bonellia[4]. I would suggest, therefore, that in *Scalpellum scalpellum* and Cirripedes of its type all larvæ are potential hermaprodites (instead of female as in Bonellia), but those which become parasitic on adult hermaphrodites develop as functional males only and go no farther. Since the breeding system involving complementals is widespread in the Cirripedes, it may further be suggested that this type of sex determination is primitive for the group.

Albert Hall Acoustics

THE changes made to house the recent season of Promenade Concerts have affected the appearance more than the acoustics of the Albert Hall. The subject has been discussed periodically ever since the Hall was built, but the oval ground plan and the great height are insuperable difficulties with reflecting surfaces. Most of the changes proposed, including that of Bagenal and Wood illustrated on p. 65 of their "Planning for Good Acoustics", showing the source of sound placed far above ground-level, attempt to preserve the full seating capacity of the Hall. Recently conditions have changed considerably. For some time pugilists and politicians have been the chief users of the full capacity of the Hall. But now there are a number of recognized sporting-centres in London and politicians can address even larger audiences through the radio. Musicians have, however, lost the Queen's Hall and other concert halls.

It would appear, therefore, that, when construction takes the place of destruction, the principle of 'divide and rule' could with advantage be applied to the recalcitrant acoustics. One half of the building could be used for a concert hall seating about five thousand, the number said to be needed for unsubsidized orchestral concerts in London. The remainder could be cut up to house smaller concert and recital halls, studios, a musical library, cafés, cloak rooms, ventilating plant and other needs of a musical centre. The volume of the Hall is adequate for all these needs. Although the fan shape is one of the simplest to plan acoustically, suggesting a division into wedge-shaped sections, like cutting a cake, the actual details of the division would be more a matter of structural engineering. Drastic changes of ground plan are essential. The most difficult acoustical problem would be the sound insulation of the different halls so that, if needed, they could be used at the same time. The division of the Hall would provide excellent support for roof gardens, like some of those in New York, where music and drama could be enjoyed out of doors in the summer time. The gardens would be well out of the range of appreciable traffic noise, and carefully planned stone wall screens could act as sound reflectors as in the typical Greek theatre.

Success would probably be best ensured by employing engineers and physicists under the direction of a fanatically functional architect.

A PHOTOGRAPHIC METHOD OF ESTIMATING THE MASS OF THE MESOTRON

By Dr. D. M. Bose and Biva Choudhuri
Bose Institute, Calcutta

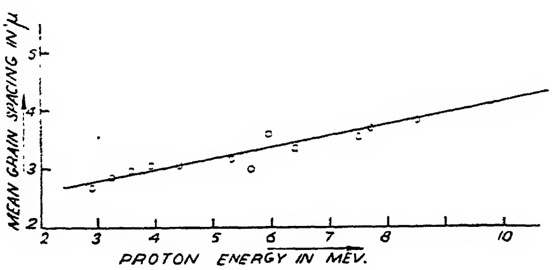
In a communication in Nature[1] it was concluded that the heavy ionization tracks found in Ilford New Halftone plates kept exposed to cosmic rays at Sandakphu (12,000 ft.) were chiefly due to mesotrons. The basis of this conclusion was a comparison of the mean grain spacing and curvature of tracks due to cosmic rays with tracks due to protons of known energies on similar plates.

In the present communication an account is given of a method of estimating the mass of these particles, presumably mesotrons. Usually three independent measurements are necessary to specify completely a moving charged particle, namely, its charge, mass and velocity. We start with the assumption that these particles are singly charged. We have determined the energy of these particles from their mean scattering and also their velocities as function of the mean grain spacing along their tracks. For the first we have made use of the formula recently given by Williams[2] connecting the mean energy W and the mean scattering $\bar{\theta}$ suffered by fast charged particles in a thickness t of a medium containing N atoms per c.c. with nuclear charge Ze. As will be seen later, the energies of such particles vary between 0·4 and 1·6 Mev., and the nuclear charge is low, so that the scattering is taken to be due only to Coulomb forces and that the use of Born's approximation is valid, and that the non-relativistic form of the equations can be used.

The mean deflection

$$\bar{\theta} = \{3{\cdot}69+0{\cdot}28 \log_{10} (Z^{4/3} \rho t/A\beta^2)\} \frac{Ze^2}{W} \sqrt{Nt} \ldots (1).$$

Since the photographic emulsion is heterogeneous in composition, we have assumed that the actual distribution of atoms of different kinds in it is replaced by one kind of atom of mean nuclear charge Ze and mean atomic weight A. These are estimated from a knowledge of the density ρ of the emulsion and its percentage composition as given by Wambacher[3]. It is found that $\rho=2{\cdot}89$, $Z=6{\cdot}2$ and $A=12{\cdot}6$. We have measured the total deflection θ suffered by a group of particles having a given mean energy and traversing a total thickness of emulsion varying between 0·33 and 0·09 cm. For the large number of encounters which take place under such conditions, $\frac{|\theta - \bar{\theta}|}{\bar{\theta}} \ll 1$; that is, for θ in equation (1) we can write θ. Having thus determined the value of $W=\frac{\mu}{2}\,\overline{v^2}$ of the mesotrons corresponding to a given mean grain spacing, we proceed for the second part of the investigation to determine the kinetic energy of protons having the given mean grain spacing along their tracks, in the same kind of emulsion. Our procedure is based upon the assumption that in such emulsions particles of different masses, but with the same charge and the same initial velocity will have the same mean grain spacing along their tracks. According to the accepted theories, the ionization loss of different particles with the same charge in a given medium depends only on their velocities. Such particles may have different ranges, but the mean grain spacing along their tracks will be the same, if they start with the same initial velocity.



We have prepared a calibration curve showing the mean grain spacing along the tracks of protons as a function of their initial energies. For this purpose we have produced recoil protons in the emulsion using neutrons of different energies produced by a radium-beryllium source. It has been found[4] that these neutrons have several discrete energy values; our own results are in general agreement with those of Blau[5], who also used the photographic plate. We have used proton tracks with ranges in air of 10–90 cm. and of energies between 2·25 and 9 Mev. After several trials we found that the most satisfactory calibration curve could be obtained by plotting the mean grain spacing along the proton tracks belonging to each energy group as a function of the corresponding energy. The calibration curve in the accompanying graph was found to be a straight

Mean of A and C $(160{\cdot}2 \pm 4{\cdot}3)\ m_0$

A : Plate kept in Sandakphu (12,000 ft.) under air.
B : Plate kept in Sandakphu (12,000 ft.) under 20 cm. of water.
C : Plates kept at Phari-Jong (14,500 ft.) under air.

line, and we felt justified in extrapolating it to the values of mean grain spacing found in the cosmic ray plates.

In the accompanying table are the data from which the mass of the mesotron has been estimated. We have divided the tracks on the plates into groups, the range of variation of the mean grain spacing in each is given in ii (*a*) and the resultant mean in ii (*b*). The total length of tracks in each group is given in (iii), and their total deflection due only to multiple scattering in (iv). The mean energy of each group of mesotrons as calculated with the help of formula (1) is given in v (*a*) and of protons with the same mean grain spacing as obtained from the accompanying graph in v (*b*). The last column gives the calculated values of the mesotron mass. It will be seen that fairly consistent values of μ are obtained from (*A*) and (*C*) in plates exposed under air, while with those obtained from (*B*) for plates exposed under 20 cm. of water, the values are consistently high. This is understandable, since by collision of the high-energy neutrons present in the cosmic ray with the hydrogen atoms contained in the 20 cm. layer of water, fast recoil protons are produced, and the scattering observed is due to a mixture of such protons with the mesotrons.

The method described above is a statistical one based upon a number of assumptions, averages and extrapolation. The presence of protons cannot be entirely excluded from such measurements. It is surprising, therefore, to find how the measured values of μ fall within the range of the best determinations by other methods[6]. It remains to be investigated whether the photographic method can be further improved into a precision method of determining the mass of μ. The results obtained are important in other respects; it has enabled us to verify our previous surmise that the star-like tracks found in our photographic plates are due to secondary mesotron showers produced chiefly by cosmic ray neutrons. This and the presence in such showers of three-, four- and five-star tracks in approximately equal numbers are results which do not appear to be capable of interpretation in terms of existing theories.

A detailed account will appear in the *Transactions of the Bose Institute.*

[6] Bethe, *Phys. Rev.*, 57, 260 (1940) estimates that the most reliable measured values of μ lie between 150 and 220 m_0. When certain corrections are made, it is expected that the former will be increased by at least 10 per cent.

FOOD AND INCOME

By D. CARADOG JONES

UNIVERSITY OF LIVERPOOL

A REPORT, published under the title "Food and the War", by the Edinburgh Branch of the Children's Nutrition Council*, gives an account of a study of the expenditure of a sample of families of the unskilled labouring class, made by voluntary workers during the period April–November, 1940. The object of the inquiry was to determine whether their incomes sufficed to purchase for these families an adequate diet as judged by two well-known standards, the first defined in the Report of the British Medical Association's Committee on Nutrition (1933), the second in the League of Nations Report on the Physiological Bases of Nutrition (1936, II B.4). Since the families were chosen solely on the ground of readiness to co-operate and lowness of income—43 per cent had less than 50*s*. a week coming in and only 11 per cent had £4 or more—the main result of the investigation might be regarded as a foregone conclusion. Despite this fact and the small size of the sample studied, the figures and the inferences drawn from them are not without interest.

Of the 103 families visited 12 were on public assistance; in 38 the head was absent from home on war service, in 25 the wage earner was a labourer; the remainder are classed simply as "others". By means of a questionnaire particulars were obtained from all but two of these families as to their composition by sex and age and as to their expenditure on certain "fixed charges": rent and rates, lighting and heating, insurance and any regular payments to a doctor. The total sum thus accounted for was in each case deducted from income and the balance was compared with the amount of money needed to feed the family adequately at 1940 prices according to the British Medical Association standard. It was discovered that 51 out of 72 families which supplied full information on this point, that is, 71 per cent, would have had insufficient money to pay for an adequate diet even if all the remaining balance had been spent on food. Actually, when the purchase of other necessities is brought into the account, only 10 per cent of the families sampled had enough money left to purchase an adequate diet. Using an American rating scale of somewhat doubtful accuracy a further estimate was made to the effect that the diets of 40 families out of 53 tested were less than 50 per cent adequate. The report itself gives tables, but the above are the broad conclusions.

Detailed records of their expenditure were kept for periods of one to three weeks by 76 families. Analysis of these budgets revealed that rather more than one half of the families sampled over-spent their income each week. This is on the perhaps doubtful assumption that all sources of income were disclosed to the investigators. Some ran up bills, paying a little off as they could and the debt growing bigger each week; others, in particular those with a member of the family in the Forces, received help from relatives.

In the majority of families the proportion of income spent on non-essentials was very small, but it increased as the income rose. Expenditure on necessities other than food included relatively large

*Children's Nutrition Council, 37 Esslemont Road, Edinburgh, 28 pp., 3*d*.

instalments towards the hire-purchase of clothes and furniture. The temptation to buy wardrobes is said to be strong on account of the lack of proper provision for hanging clothes in houses put up under recent schemes. One instance is quoted of instalments paid by the same family on three wardrobes in two years: two were removed owing to failure to continue the weekly payments. About three out of every four families investigated also paid regular premiums to meet the cost of burial, in some cases amounting to more than 7*s*. a week. This is a serious drain on slender resources—enough to "pay for a funeral every year".

Returning to the main theme of the inquiry, the writers suggest that, apart from education in regard to the value and preparation of different foods, much might be done to solve the diet deficiency problems raised in this study by a wide extension of communal feeding, of the national milk scheme, and of all social services relating to food.

USE OF GLASSES AS AN AID TO VISION

By R. Weatherall
Eton College

As part of an investigation to discover whether physical defects among children increase with age, M. V. Marshall organized a survey of the use of glasses by children attending school in a representative American city.[1] In all, the survey covers 8,204 children ranging in age from kindergarten to the twelfth grade; that is, 5–17 years. The results show an almost uninterrupted increase in the use of glasses, from 2·7 per cent among the youngest, to 15·7 per cent around the age of twelve, and 23·7 per cent by the time the pupils are leaving school. An additional proportion of the children, ranging between 2 per cent and 7·5 per cent, had been advised to wear glasses, but were not doing so.

Children do not take kindly to wearing glasses when they first begin to take an active part in school games, and when they become conscious of their own personal appearance. Allowing for such personal factors, there are unexplained checks in the use of glasses around the ages of ten and fifteen. Also, personal factors alone can scarcely explain the wide discrepancy in the separate figures for boys and girls. Between the ages of twelve and seventeen the proportion of boys wearing glasses varies irregularly between 12 and 18 per cent, while for the same age-groups the girls show an increase from 17·7 to 32·8 per cent.

Altogether, the figures are striking enough. They show clearly that the need for glasses increases rapidly during a pupil's school life, so that by the age of sixteen about 1 in 7 of the boys, and 1 in 3 of the girls, are using artificial aids to vision. Even so, it is very probable that a still higher proportion of these children must be considered as having eyesight below normal. The figures revealed by this survey agree fairly well with those obtained by a smaller one which I carried out on boys attending a school in England. They give some measure of the magnitude of the problem of defective eyesight at the present time.

FATIGUE TESTS OF WELDED JOINTS

The publication by the University of Illinois Engineering Experiment Station of the results and conclusions derived from an investigation carried out there on welded joints in structural steel plates is but the first instalment or progress report of the proceedings*.

The primary object of those responsible was to obtain reliable information on which to base specifications governing the design of welded structural members subjected to reversed or pulsating stresses. The lack of knowledge of the fatigue strength of welded joints has been the principal deterrent to their adoption in the fabrication of bridges, and it was clear that tests on the largest practicable scale would have to be made before this method of construction could be placed on a satisfactory and reliable basis. Realizing this, the Welding Research Committee of the Engineering Foundation organized a special committee representative of all engineering interests to plan and carry out the work.

As used in this report, the term fatigue strength of a member refers to the maximum stress in the stress cycle which caused its failure at a stated number of cycles when the ratio of the minimum to the maximum stress had a stated value. While it is not possible to specify the stress which will cause failure at a predetermined number of cycles, it was practicable to estimate the stress cycle which would disrupt the specimen at the desired stage in the test. This was the procedure adopted and three kinds of cycle were used: (1) from a tensile stress to an equal compressive stress; (2) from zero stress to a maximum tensile stress; (3) from a maximum tensile stress to a minimum tensile stress of half the value. These gave ratios r, of -1, 0 and $+0{\cdot}5$ respectively, and for each value of r, seven identical specimens were tested: three so as to fail at 100,000 cycles, and three at 2,000,000 cycles, the seventh being a spare to be tested as desired after the other six tests had been completed.

* University of Illinois Engineering Experiment Station. Bulletin Series No. 327: Fatigue Tests of Welded Joints in Structural Steel Plates. By Wilbur M. Wilson, Walter H. Bruckner, John V. Coombe and Richard A. Wilde. Pp. 86. (Urbana, Ill.: University of Illinois Engineering Experiment Station, 1941.) 1 dollar.

In this way, four different investigations were carried out, namely, fatigue tests of butt welds in carbon-steel plates; comparisons of the strengths of welded and riveted joints in low-alloy steel plates; the effect of periods of rest upon fatigue strength of butt welds; and the influence of transverse fillet welds upon fatigue strength. Tests were made of specimens in the as-welded condition and of others with the reinforcement planed flush with the plate and of others again with it ground flush. In each category there were specimens which were stress-relieved by being heated to 1,200° F. for one hour and then cooled in the furnace while others were not stress-relieved.

Considering that the welds under test may be fairly regarded as having been made under as nearly as possible ideal conditions, the results indicate that when suitable allowance is made for variations in quality, the dependable strength of welded joints and plates weakened by transverse welds is still quite moderate. The details are too numerous to summarize, but as examples, some of the results at 2,000,000 cycles may be cited. Butt welds in ⅞-in. carbon-steel plates in the as-welded condition gave 14,400, 22,500 and 36,900 lb. per sq. inch in the three classes of cycle. The corresponding figures for machined-off specimens of classes 2 and 3 were 28,400 and 43,700 and for ground-off specimens of class 2 were 26,300. Stress-relief did not appear to affect fatigue strength, and periods of rest showed no advantage. Carbon-steel plates with one transverse fillet weld gave an average of 18,900 and with two welds 13,100 lb. per sq. in. The character of the bead had some effect on the figures, but for a given base metal the variation did not exceed 5 per cent.

FORTHCOMING EVENTS

Saturday, August 30

BRITISH INSTITUTION OF RADIO ENGINEERS (at the Federation of British Industries, 21 Tothill Street, London, S.W.1), at 3.15 p.m.—Mr. G. A. V. Sowter: "Applications of High Permeability Magnetic Alloys to Electronic Devices".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DISTRICT EDUCATION OFFICER (man or woman)—The County Education Officer, County Hall, Hertford (September 6).

PUBLIC ANALYST and an OFFICIAL AGRICULTURAL ANALYST—The Clerk of the Berkshire County Council, Shire Hall, Reading (September 9).

LIBRARIAN—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (September 10).

CONSULTANT PSYCHIATRIST and an EDUCATIONAL PSYCHOLOGIST—The Director of Education, Education Office, Chapel Street, Salford 3 (September 13).

COLLEGE LIBRARIAN (woman)—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (September 13).

POWER STATION SUPERINTENDENT—The Town Clerk, Town Hall, Halifax (September 15).

BOROUGH ELECTRICAL ENGINEER—The Town Clerk, Town Hall, Woolwich, London, S.E.18 (endorsed 'Appointment of Borough Electrical Engineer') (September 15).

LECTURER IN BOTANY, with subsidiary Zoology—The Principal, Technical College, Kingston-upon-Thames.

LECTURER IN ELECTRICAL ENGINEERING—The Principal and Organizer of Further Education in Rugby, College of Technology and Arts, Rugby.

POST-GRADUATE TEACHING SCHOLAR (Experimental Zoologist) IN THE DEPARTMENT OF ZOOLOGY—The Secretary, The University, Edmund Street, Birmingham 3.

NATURE

SATURDAY SEPT. 6, 1941

ANGLO-AMERICAN TECHNICAL CO-OPERATION

THE broadsheet, "America and Britain", which has recently been issued by Political and Economic Planning (P E P) directs attention to some of those technical aspects of co-operation between Great Britain and the United States, which are as important for the implementing of common policy and the achievement of common purposes as the great traditions and ideals on which Anglo-American co-operation is ultimately based.

Although the vivid realization of common danger and the need for joint measures against it has provided a stimulus to Anglo-American co-operation, it is not the only one. Already the question of dealing with food surpluses and their relation to European needs after the War has been responsible for joint planning and co-operation. The United States is vitally interested in the work of both the Leith-Ross Committee and the Willingdon Commission, and the agreements with the Governments of Australia and New Zealand on the disposal of their surplus food production recently announced by Mr. Arthur Greenwood are part of a great scheme of international reconstruction, the success of which depends on common action with the United States and with the Latin American republics.

Developments in this sphere providing the means by which the United States can, in accordance with President Roosevelt's pledge of March 15, play its great part in the period of world reconstruction for the good of humanity, cannot but have a profound bearing on the problem of the formal organization of Anglo-American co-operation which is the theme of Mr. Streit's "Union with Britain Now". Indeed they may well provide the experience upon which any federation proposals can be most securely based, and seen from one angle represent experiments in keeping with the traditions of both democracies from which new methods can be most surely developed.

There are other fields also in which this experience is being gained. A notable article by Prof. A. V. Hill in *The Times* has described the way in which organization is being developed for an effective Anglo-American partnership in research. Already last summer, as a result of an approach by Lord Lothian, President Roosevelt invited the British Government to send a mission to the United States to consider ways and means of sharing scientific and technical information between the United States Services and the National Defense Research Committee on one side and the British Services and scientific organizations on the other.

The very satisfactory arrangements ultimately made as the outcome of Sir Henry Tizard's mission have played an important part in creating good will and enlisting the co-operation of American men of science, and the liaison now established will become increasingly important as the Lease-Lend Act operates.

The possibilities of co-operation in this way are as yet barely realized by the majority of scientific workers, and whether in research or the supply of skilled personnel, collaboration between British and American men of science offers immense advantages to both countries, in peace as well as in time of war. The advantage to the United States of British experience in war research and in operations against the enemy should be as obvious as is that of the vast scientific and technical resources of the United States to Great Britain. What is less apparent is that the increasing dependence on American supplies to which the Lease-Lend Act commits us implies in the long run the acceptance of United States patterns, often adapted from Allied types, or in the light of Allied experience, as the basis of the army and air force equipment of all the forces using American supplies.

An understanding between the United States and the British Commonwealth on the standardization of equipment is accordingly essential, with agreement as to the best form of mechanisms and devices of warfare. This, with the establishment of rapid transport both ways for essential information, experimental equipment and key personnel is one of the most important immediate objectives on the scientific and technical side. Following this might come some agreement as to the location of research on different types of problem, the more immediate problems being tackled in Great Britain, the longer-range problems in the United States, for example.

The many able men and women attracted to Washington by the New Deal provide the United States with an invaluable source of staff for the war-time organizations, and the strengthening of the United States Civil Service in the last ten years has also been a major factor in enabling the administration to deal with its new tasks. As is increasingly recognized in Great Britain, even more important than the new powers and new machinery of government is the way in which they are used. This is primarily a question of personnel, and there is little doubt that both countries could profit by use of the other's experience in such fields as labour policy, the handling of man-power, and all questions of priority, both in respect of man-power and materials. Co-operation indeed in this field offers the only prospect of obtaining the full efficiency involved in maintaining the proper balance between the British armed forces and the overseas workers. The former can only be maintained at its level of nearly four millions because the United States and the Dominions provide its supplies. The establishment in London and Washington of a common research organization to consider the economics of the British Empire and the United States in this way might be a useful practical recognition of such unity and powerfully assist the elimination of bottle-necks.

Even in a country as wealthy as the United States, some shortages are bound to occur—probably with non-ferrous metals such as manganese and chromium and the special steels—and some rationing of raw materials on the British model may be required, with a thorough discard of the idea that monetary means can secure smooth and rapid production for war. Already it is recognized that some restriction of consumption so as to divert output from the non-essential industries to war production is necessary in the United States as in Great Britain, and the whole field of war economy offers possibilities of pooling experience that should promote co-operation and understanding for peace purposes as well as for those of war.

This is notably true in certain special fields such as those of food policy and social security, to which particular attention is directed in the P E P broadsheet. It was increasingly recognized before the War, on both sides of the Atlantic, that the provision of a minimum diet and standard of life ought to be a first charge upon the national income. The supply of milk to all children in schools and junior instruction centres in Great Britain under the Milk Act of 1934 has been followed by war-time measures designed to prevent the fall in food standards from affecting the diets of poorer people. The American Food Stamp plan was an ambitious experiment with the same end in view of increasing the consumption of the protective foods, dairy products and fruit, of which the poor consume so much less than the richer classes.

Wide adoption of certain of the measures, such as school feeding, introduced in Great Britain, might effectively raise the low dietary standards in some parts of, and among certain classes in, the United States. Moreover, as Mr. Winant emphasized in his valedictory report to the International Labour Organisation, war increases the need for social services to cushion the shock of reductions in consumption and drastic changes in popular modes of life. The creation in peace-time of a comprehensive system of social security services is a great asset both to Great Britain and the United States, and one of the really solid achievements of the New Deal has been the application of the principles of British social legislation in a thorough and promising way.

The importance of developments in this field, notwithstanding the controversy persisting on both sides of the Atlantic on the administrative and financial problems involved, should not be overlooked. The extension of the unemployment and health insurance schemes in Britain, for example, removes one of the causes of lower middle-class insecurity which in Germany contributed to the rise to power of the Nazis, and may also facilitate a new social and political solidarity apart from its contribution to the establishment of the third freedom of President Roosevelt's speeches. Beyond this, the compromises which have been reached at different points reflecting the different balance of forces in the two communities cannot disguise the common pattern leading up to and flowing from every new social measure in Great Britain and the United States.

Many of the developments which have taken place on both sides of the Atlantic are scarcely more than improvisations to deal with urgent needs. This is notably true of education, where neither of the two great democracies has an entirely satisfactory record. In both countries, however, there have been developments, such as the country schools established as a result of evacuation in Great Britain, and the Civilian Conservation Corps in the United States, which hold great promise for the future integration of town and country and afford opportunities for pooling experience and for the growth of mutual understanding.

These wide fields over which Anglo-American co-operation is already proceeding, and the immense range of common experience, are a powerful reason against hastily forcing the organization of formal co-operation into any set mould or union. That effort should be deliberately directed to the examination of the possibilities and the testing of alternatives is all to the good, but the utmost care should be taken to avoid any step which might impede rather than promote effective collaboration. For this reason with such investigation a nation-wide campaign of education should proceed even in the stress of war, supplementing the brilliant efforts of leaders on both sides of the Atlantic, to interpret and understand the differing interests and points of view of the two peoples as well as their common ideals, traditions and heritage. Even the domestic post-war reconstruction plans in Great Britain under the Ministry of Works and Buildings and the Cabinet Committee on Reconstruction and War Aims are being followed with keen interest in the United States, where the resolution before the Senate proposing the establishment of a "Post-Emergency Economic Advisory Commission" to plan for full employment indicates that people in the United States are also beginning to think and plan in response to the same challenge.

If there is interest in questions of domestic reconstruction, this is even more true in international planning, where many thorny questions will require much thought and careful consideration. The visits of leading British citizens to the United States and the dispatch of American missions to Britain on such varied questions as economic mobilization, scientific co-operation, health services, A.R.P. and fire-watching may help to cross-fertilize opinion and prepare the ground for what must be comprehensive plans. The presence of many European refugees in both countries and such developments as the transference of the headquarters of certain international trade unions to Britain, and the recent conference of representatives of Allied Governments in London should also assist in the formulation of sound proposals for European reconstruction.

The Eighth American Science Congress in May 1940 favoured an inventory of world natural resources and the formulation of a general policy and specific programme of action to promote mutual conservation and prudent utilization of natural resources for the welfare of all nations in the interest of permanent peace. The report of a round-table conference in February at Princeton, New Jersey, under the auspices of *Fortune*, indicates that influential American opinion already recognizes that American help is essential to eliminate the growing burdens of an armament economy. The majority favoured the acceptance of commitments on behalf of a New Order of Free Peoples resting on recognition by the State of the unique value of human personality, restriction of national sovereignty, and creation of effective international institutions.

The report went on to outline a programme of war-time co-ordination, including the formation of an Anglo-American Technical Board to work out common specifications, the creation of a United States Department of Economic Defense, and joint purchase and storage of raw materials by the two Governments, the gradual creation of an Anglo-American Economic Council, and the appointment of an official commission to prepare a programme of post-war demobilization. The problems of the latter period are considered at length, and suggestions advanced for American contributions to the restoration of a world economy include the continuance of the low tariff policy and the resumption of foreign lending on behalf of a general reconstruction policy.

Whatever form the organization of the new order of free peoples may take, this report suggests that the United States should at least participate in machinery for the settlement of international disputes and in a system of effective sanctions against aggressors, accept the responsibilities of a creditor

nation, conclude agreements regulating domestic policies that might injure other peoples, and participate in agreements for the reduction of armaments. This is weighty evidence of American support for the Atlantic Charter.

Both in Britain and in the United States scientific workers were among the first to realize the true nature of the Nazi menace and its attack on freedom of thought and investigation. They will appreciate the enduring values which community of tradition and doctrine give to the Anglo-American co-operation now so rapidly developing. They will not be the less zealous in their efforts to evolve in scientific and technical matters the machinery of effective co-operation, and to assist in the educational work which makes for understanding between the two communities for this growing evidence of some greater and more enduring co-operation after the War, in the tremendous task of establishing a world order to serve more abundantly man's noblest heritage and highest aspirations as well as his material needs.

A JERSEYMAN AT OXFORD

A Jerseyman at Oxford
By Robert Ranulph Marett. Pp. xi+346+4 plates. (London, New York and Toronto: Oxford University Press, 1941.) 15*s.* net.

TO-DAY it is increasingly the custom among men and women, if they count themselves to have done or seen something, to write their autobiographies, and honesty compels the critic to own that they are seldom successful. But this book is an outstanding exception. Here is a man who has "warmed both hands beside the fire of life", and in his seventy-fifth year that fire has not yet shrunk. He writes with zest and gusto *currente calamo* out of the fullness of a mind produced not only by reading and disciplined study, but also by knowledge of many friends and many countries, together with many and varied experiences such as come to a man who prefers the struggle to the prize, and can throw himself wholly into what he happens to be doing.

Dr. Marett in comparison with the vast majority of his fellow-countrymen, as he would himself be first to confess, has been a fortunate man from the start. Born of good family, reaching back through many generations of service in Jersey, he was brought up in a good home with wise and cultured parents in a beautiful place set fair in the freedom of sky and sea. Nature in her kindness endowed him with good brains, good memory, lively imagination and abounding physical vigour. He has been excellent in games which have interested him, particularly golf: he has been, and is, a good shot. Eyesight, strength and nerve have not failed him in more than seventy years. When as a young man just down from Oxford he was free to travel abroad, he enjoyed long spells in France, Germany and Italy. If Paris and an aristocratic home, poor but proud, bored him, in Germany he was able to move in the Junker set, to dine once in the Kaiser's presence, to frequent the universities, and to be adopted by the American colony. In Italy he was under the patronage of Lord and Lady Dufferin, and all doors were open to him. Antiquities, pictures, the best company, rides over the Campagna, Rome, Naples, Sorrento —"a rapturous year" he rightly calls it. And what a mixture of interesting people for a young man to meet—Lord Dufferin and Lord Hartington, Lanciani and Dr. Axel Munthe, Buffalo Bill and Prince Napoleon Bonaparte, even King Umberto and the Pope himself—the last in compromising circumstances. Some will pretend to look down on this sort of thing, but these advantages are very real for a young man who knows how to mix, and does not allow his head to be turned.

Not only has he been fortunate, but also lucky: in the lottery of life luck counts too. Lucky, when as a child of eight he was rescued from his burning house, lucky when on the Riffel Alp he fell off a cliff into a dead pine-tree which held, and on the Langdale Pikes off a crag forty feet into soft snow; lucky again when, feeling ill in Oxford, he pulled by chance the door-bell of a doctor who could diagnose meningitis at sight, lucky in the last war when in a black-out he fell between a moving train and the platform, and escaped hurt, but not maimed, and twice when he came very near to German bombs; lucky when but the other day he received thirty-seven pellets at close range in his leg, and did not lose it. In all these cases the dice might so easily have fallen otherwise.

This book begins rightly with his island, his ancestors and his home: there emerges the picture of a boy with sport in his blood, but sport going along with natural history. A good preparatory school, and Victoria College in a good period follow, the picture now of a boy picking up classics without taking too much trouble. A Balliol Exhibition is won, Benjamin Jowett enters his life, he becomes in his own words a "smug", or "a natural extrovert imposing upon himself an

introverted character by sheer will". A strange type of introvert, who made hosts of friends, became secretary of the Union, and belonged to eighteen societies. By dint of reading by the light of nature he got a first in Mods. and the Chancellor's Latin Verse. A whole chapter is rightly given to Greats, for it made him finally what he is: Jowett and Lewis Nettleship between them made him a Platonist, and Strachan-Davidson set him to read "Custom and Myth". In spite of meningitis he got his first for his brilliant promise, and passed on to his *Wanderjahre*, then a year as maid of all work at Balliol, and finally his Exeter fellowship. The interest of autobiography lies not in telling what a man is, which in this case all the world knows, but how he came to be what he is. Exeter has been his life since: he has held all offices there, and is now its rector, unanimously elected, unanimously prorogued to the full limit. In this book the whole of his wonderfully interesting activities is written at length. For two-thirds of his time he has taught philosophy, in the remaining third he has made a world-wide name in anthropology; but whether he has done his more valuable work as a famous pioneer in a new science, or in the quiet guidance and shaping of the minds of successive generations of young men is unknown to him, as to all.

Here at the very end fortune has proved adverse. Almost in the same hour he lost his eldest son in the *Glorious*, and his home and all his possessions in Jersey. It shows what manner of man he is that he has in bereavement and loss written this delightful book, full of happiness, crowded with interest, and without one unkind word spoken of any—the splendid record of one who through a long life has set himself "to strive, to seek, to find and not to yield". CYRIL NORWOOD.

DEVELOPMENT OF MATHEMATICS IN THE UNITED STATES

(1) A Semicentennial History of the American Mathematical Society, 1888–1938

With Biographies and Bibliographies of the Past Presidents. By Raymond Clare Archibald. Vol. 1: History. Pp. x+262. Vol. 2: Addresses. Pp. v+315. (New York: American Mathematical Society, 1938.)

(2) Bibliography of Mathematical Works printed in America through 1850

By Louis C. Karpinski. Pp. xxvi+697. (Ann Arbor, Mich.: University of Michigan Press; London: Oxford University Press, 1940.) 33*s*. 6*d*. net.

(1) THE American Mathematical Society anticipated its semicentenary, which fell in 1938, by appointing a celebration committee ten years in advance of that date. The semicentenary was a great social event; it was also the occasion for the issue of two handsome volumes, a history of the Society and a set of addresses.

In Prof. Archibald's history, a detailed account of the birth and growth of the Society is followed by biographies and bibliographies of the secretaries and the presidents. The early chapters describe an amazing advance, of which the character is revealed most clearly in abortive negotiations with the *American Journal of Mathematics* which preceded the establishment in 1900 of the *Transactions* of the Society. To the older men, America was an intellectual dependency of Europe, and the ambition of an American journal was to attract contributions from the great scholars of the Old World; a younger generation was confident of its native powers. A stroke of diplomatic genius on the part of Maxime Bôcher drew the sting from the dispute, no resentment remained, and when in 1925 the great depression threatened the existence of the *Journal*, the Society came willingly to the rescue.

Written before 1939, the story of the struggle to maintain international collaboration in mathematics makes heart-rending reading to-day. We must derive what comfort we can from knowing that it was a story of Anglo-American co-operation, for the London Mathematical Society, in our more intoxicated country, was a partner with the American Mathematical Society in protest against the blind French vindictiveness which organized an allied congress at Strasbourg in 1920 and would have excluded Germans from Bologna so late as 1928 if the committee arranging the latter congress had not defied the ban. But success too long delayed is illusory. "You shall not come" of 1920 and 1924 became "We will not come" in 1936. It is only in the most formal sense that Prof. Archibald's assertion that "No political taint marred the delights of the congress at Oslo" is to be interpreted. The Germans made no pretence at co-operating, the Russians decided at the last minute not to attend and rapid changes of programme became necessary in consequence, and the time of

year was exceptionally inconvenient, we were given to understand, for the French. The Congress was international in constitution, and its delights were truly unmarred, but there were few beside Americans, British and Swiss to share the unmarred delights with their Scandinavian hosts. In all but name the series of international congresses which began at Zurich in 1897 came to an end there in 1932, for the epilogue of Oslo in 1936 was less in the spirit that inspired the early meetings than was the prologue of Chicago in 1893.

Prof. Archibald's story of the rise of the American Mathematical Society is a model of exact information attractively presented. He was fortunate in the completeness with which records had been kept; with the best will in the world, few historians can hope to imitate him. More remarkable as a personal achievement is the compilation of biographies. Regarding men of the standing of G. W. Hill and Simon Newcomb, Oswald Veblen and G. D. Birkhoff, sources are plentiful and the biographer's task is selection and composition; bibliography always presents countless little problems, but these are meat and drink to Prof. Archibald. Where his passion for accuracy and completeness has found full scope is in the reconstruction of the characters and doings of the less distinguished of his subjects; there are no gaps in his series, and even his collection of photographs is complete.

Enjoyment of an art is one of the good things of life. If ignorant and facile it cannot be rated highly, but if it is informed, critical and appreciative it is the very stuff of which civilization is made. It is not to be measured by creative ability; to react to the subtle cadences and alliterations of great prose is better than to feel smug satisfaction in composing a scrap of doggerel. If the artist covets the praise of his peers, that is because their judgment involves an understanding of technical success, not because it is they only whose receptive emotion is worth arousing. Perhaps no one has seriously maintained that poetry should be read only by poets, ballet watched only by choreographers. The view that higher mathematics has no contemplative side but exists only for its practitioners may be less demonstrably absurd, but it is certainly ungrateful. For the past hundred years, the societies through which mathematicians have reached a public outside their own lecture-rooms have been utterly dependent on the support of long-forgotten members who have no place in the history of mathematics and who asked in their time nothing more than to promote the study of mathematics and to facilitate the work of mathematicians. From London and Palermo to New York and Madras the story is the same, not of a few great men supplying each other's needs, not of braggart mediocrities indulging in mutual admiration, but of sincere and modest enthusiasts. Prof. Archibald has conferred on the devoted servants of the American Mathematical Society that measure of survival to which they are entitled, and in doing so he has not attempted to exaggerate their importance as mathematicians. It must be confessed that in one sense his own kindly disposition and his familiarity with almost all the men of whom he writes have disqualified Prof. Archibald: he is not the impartial biographer, recording faults and foibles as well as merits and achievements; we cannot learn from everybody's friend that this man was vindictive, that man conceited, and a third an amiable but inflexible dictator. But mathematicians are as liable as other people to disagreeable traits, and when the nearest approach to censure in twenty-six sketches is in the quotation "For the apparent eccentricities of his private life there must have been some sound reason, creditable to him", we know that only one aspect of each sitter is being drawn. None the less, the portraits that emerge are differentiated and vivid.

Before we turn from this volume we must make mention of the preface, where all that is most likeable in Prof. Archibald and most admirable in his work finds uncalculated expression.

Of the volume of addresses little can be said unless each address is to have its own notice. The contributions are as follows: E. T. Bell: fifty years of algebra in America; J. F. Ritt: algebraic aspects of the theory of differential equations; N. Wiener: the historical background of harmonic analysis; E. J. McShane: recent developments in the calculus of variations; T. Y. Thomas: recent trends in geometry; R. L. Wilder: the sphere in topology; G. C. Evans: Dirichlet problems; J. L. Synge: hydrodynamical stability; G. D. Birkhoff: fifty years of American mathematics. The nine addresses all tell the same astonishing story of progress; in the first and last we follow it step by step; in the others we join the leaders in the forefront of their advance. The country which, if Hill and Newcomb must be ceded to the astronomers and Gibbs to the chemists, had produced by 1888 only one mathematician, Benjamin Peirce, had become in 1938 the equal of any country in the world, and is ready, if European civilization in its collapse buries England in the ruins, to fulfil alone the task of preserving and enriching the human heritage. The transformation was not the work of one man, but our historians agree that in the first twenty years of their half-century there was one dominating influence, that of E. H. Moore, of whom Prof. Bell says that his interests frequently changed, and with each change, mathematics in America advanced. Moore lived

to see the time when young European mathematicians were as ready to travel for inspiration to Princeton as to Paris or Vienna.

(2) The condition of mathematics in America forty years before the foundation of the American Mathematical Society is to be inferred from Prof. Karpinski's bibliography of American-printed mathematics 'through 1850', to use the convenient new idiom. In this exhaustive and handsome volume, in the preparation of which Prof. Karpinski has been helped by booklovers and librarians up and down the continent, some three thousand items are listed, and there are 908 photostatic reproductions, chiefly of title-pages. Prof. Karpinski could have spared himself much trouble by following the example of D. E. Smith's "Rara Arithmetica" and referring to figures when they are given instead of transcribing titles in these cases. It is not for the reader to complain except on the ground that there might then have been more annotations, and like all expert bibliographies this one perpetually arouses curiosity. What, for example, was the general solution to an algebraic equation which Jason H. Mahan published in 1847 under the title "Key to the Hitherto Impenetrable Secret"? Why does Prof. Karpinski assert that Hobart's "Mathematics Simplified and made Attractive, or the Laws of Motion Explained" is "doubtless a second edition" of an unlocated book which according to its copyright entry-title was "designed to shorten and make plain and easy nearly all the rules which are usually put into arithmetic"? Was Mark Duty a blind man?

In 1909 a story was current in Cambridge that a scholar of Trinity had attended the first lecture of Russell's announced course on the principles of mathematics in the belief that he was being offered intensive coaching for the impending Tripos; this story comes to mind when one finds Chittenden's edition of Motte's translation of the "Principia", which incidentally is one of the most eccentrically paged books ever printed, indexed under "General Works on Mathematics". The transcription of the title of this volume, on p. 491, illustrates how much hangs on accuracy in type, for no one without previous knowledge could interpret 'Newton's system of the world' correctly. Consistency may be the supreme bibliographical virtue, but should any rule be held proof against the exception in which the authors' names appear thus: "Todd, John, Jess, Zachariah, Waring, William, and Paul, Jeremiah"?

A few samples must be taken. The publisher who issued a primary arithmetic under the title "Hints to Mothers" not only provides evidence of the thoroughness with which Prof. Karpinski has done his work but also gives complete revenge to a famous if fabulous young coleopterist. Zerah Colburn—I take the story from De Morgan's "Budget"—pestered to explain his mode of instantaneous calculation, cried out in a huff "God put it into my head, and I can't put it into yours", but R. L. McLallen was not afraid to bring out in 1844 "A new and interesting Arithmetic, in which is explained the method that Zerah Colburn must have pursued". The word 'kindergarten' was as yet unnaturalized when the 'Chinese trangram', issued anonymously in 1817, suggested to Thomas Hill the "Puzzles to Teach Geometry" which appeared in 1848 with an approving letter from Peirce. In 1840 Peirce's interest in education took the practical and beneficent form of "An Elementary Treatise on Plane Geometry . . . printed for the use of the Blind"; we are not told whether the contents were conventional or if Peirce endeavoured to take into account the effect of blindness on the sense of form. A year later the Asylum Press followed this geometry with a table of logarithms, also printed on raised plates.

Enough has been said to show that Prof. Karpinski's bibliography is comprehensive as well as fascinating. In his very readable introduction he says: "My search, and particularly the check upon it given by various early lists, inclines me to venture the prediction that not fifty new titles which are strictly mathematical will come to light within ten years." In short, an ambitious plan has been well accomplished. The volume is indexed liberally, and an index of printers and publishers is specially to be welcomed, though there, alas, the insidious 'Pierce' is to be found.

When we look into Prof. Karpinski's bibliography not for entertainment but for evidence, when we ask the quality not of the record made but of the material recorded, what do we find? We find a devastating tale of trivialities, relieved only by translations of the "Principia" and the "Mécanique Céleste", to which, if we are generously disposed, we may add a score of minor undergraduate textbooks. We can speak with mathematical respect of the arithmetics produced in Mexico and Peru in the century and a half before 1703, the year of the first entry in English, but not of the hundreds of arithmetics that form, with surveyors' manuals, books on mensuration, sets of tables, and a few schoolbooks on algebra and geometry, American 'mathematics' until less than a century ago. North American civilization is coeval with that of Western Europe, and North America was colonized not by scourings and failures but by men of enterprise, intelligence and boundless energy. The ecological lesson is clear and menacing: the flowers of civilization flourish only in a garden, not on the fringe of a wilderness, against the walls of a factory, or in a corner of a battle-field.

E. H. NEVILLE.

THE RELATIONS BETWEEN SCIENCE AND ETHICS

By Dr. C. H. Waddington
Christ's College, Cambridge

THROUGHOUT most of history, man's concept of the Good has been rightly considered to have, or at any rate to require, a philosophical justification; that is to say, a justification dependent on the characteristics, not of a particular individual, or group of individuals, but of the world in general. This might be deduced from observation, as in the theory of Utilitarianism, or revealed by the voice of God or of conscience. During the last quarter of a century, four lines of thought have converged in an attack on this notion, and their combined effect has apparently gone far, at least among what may be called 'popular intellectual' circles, to rob ethical statements of any claims to intellectual validity. All four of these trains of thought had their origin in scientific movements. They were:

(1) The psycho-analytical, based on an examination of individual psychology, which seemed to imply that man's ethical system is a mere product of his early sexual reactions to family life, and has no more generality than that has.

(2) The anthropological, based on a comparative study of social systems, which tended to show that ethical beliefs differ extremely from culture to culture and can therefore have no general validity.

(3) The Marxist, primarily based on a study of the changing society of Western Europe, which appeared to assert that ethical systems are expressions of class forces and are epiphenomena which may be left out of account when we are considering the mechanism of social development.

(4) The anti-metaphysical of the Logical Positivists, based on the attempt to realize the 'unity of science' through a study of meaning, and issuing in the view that ethical statements have no meaning of a verifiable nature.

None of these summary statements of the four arguments is, I think, an entirely fair account of the contribution which the science in question has made to the study of ethics. But they do represent not too inadequately the sense in which these contributions have been understood among wide circles of the general reading public, including many of the younger men of science. Taken together, the four lines of attack were undoubtedly successful in persuading many people that science either has nothing to do with the formulation of ethical systems, or even is necessarily inimical to any such attempt. I wish to argue here the contrary thesis: That if these four contributions are correctly interpreted, ethical judgments are statements of the same kind—having, as the logisticians would say, the same grammatical structure—as scientific statements. I shall deny Carnap's argument that the typical ethical statement 'killing is evil' is merely a paraphrase of the command 'do not kill'[1], and "does not assert anything, and cannot be proved or disproved". I shall argue that an ethical judgment is better typified by a statement such as "You are an animal of such a kind that you must consume 7 mgm. of vitamin C per diem, and should consume 100 mgm.", that is to say, by a statement which has scientific significance.

An ethical belief must be believed by someone; and the psycho-analytical discoveries, which are concerned with the development of the ethical systems of individuals, are the most profitable basis from which to begin an examination of the scientific basis of ethics. Psycho-analytical literature is voluminous, and is couched in a somewhat anthropomorphic jargon which, while it may be an inevitable result of attempting to write in conscious language of mental processes which do not occur within consciousness, is undoubtedly not very perspicuous for the layman. But one may, with all due diffidence, mention two points which seem to emerge from it.

In the first place, ethics appears among psycho-analytical phenomena as the consciously formulated part of a much larger system of compulsions and prohibitions. Many of these remain permanently below the level of consciousness, but, all together, they make up a more or less isolable dynamic function within personality, known as the super-ego. By setting up the super-ego as the entity for investigation, psycho-analysts are abolishing, in a very radical way, the class distinctions which we commonly make among our inner compulsions, which lead us to hold that the prohibition on picking one's nose in public, for example, although often much stronger than that on lying, is less worthy of consideration. This is a piece of realism for which one can have nothing but gratitude. Moreover, it brings out clearly the very important point that one cannot avoid ethics; it is impossible to give them up like smoking in Lent. They are part of the super-ego, and the super-ego is inescapable among those present (accompanied by

the ego, the id, the ghosts of Œdipus, Narcissus and the rest) whenever we do anything.

The second of the psycho-analytical results which requires attention is more fundamental, but in some ways less straightforward. Put shortly and crudely, it is that the super-ego is formed as a result of experience of the material world, and that its propositional content has been verified in experience. There are two difficulties in the way of establishing this. First, the super-ego is being formed from the a of about six months onwards, and empirical observation at that time has a peculiar character which it later loses. "The baby", writes Joan Riviere, "cannot distinguish between me and not-me; his sensations are his world, *the* world to him."[2] The first crude notion of externality, of otherness, arises through the experience of an inability to control; and the objects which thus intrude into the baby's solipsistic day-dream are inevitably personalized, distinguished as "not-me but another person". More than that, they must appear to butt in from outside what had been thought of as all-embracing. It is, I suggest, because the development of ethics is connected with this break-up of solipsism that it has that character of other-worldliness, of absoluteness, which made plausible the anti-metaphysical comment that one can no more talk about it than about the ultimate reality behind the world's appearances. "Wovon man nicht sprechen kann, darüber muss man schweigen", said Wittgenstein in 1919, addressing philosophers[3]. His words would have been more apposite in the mouth of a mother talking to her child; but unfortunately one screams as though the devil were on one's tail; probably he is.

The second difficulty in establishing the dependence of the super-ego on experience arises in connexion with the distinction between the external and the internal, between the individual and his environment. There is first a simple confusion to clear out of the way. One finds, for example, the following sentence by Freud[4]: "Whereas the ego is essentially the representative of the external world, of reality, the super-ego stands in contrast to it as the representative of the internal world. . . ." But the context makes it quite clear that Freud is speaking here of the adult personality, at a time when the super-ego has already been formed. He is not, in calling that entity the representative at that time of the internal world, denying that at an earlier period, during its formation, it was dependent on the external world. In fact, in another place he states, fairly explicitly, the point which I wish to make: "The role which the super-ego undertakes later in life is at first played by an external power, parental authority. . . . This objective anxiety is the forerunner of the later moral anxiety."[5]

But the difficulty goes deeper than this. The author who has, perhaps, contributed most profoundly to our knowledge of the formation of the super-ego is Melanie Klein. Her view "lays emphasis on the importance of the impulses of the individual himself as a factor in the origin of his super-ego and on the fact that his super-ego is not identical with his real objects"[6]. But, she writes, "In thus regarding the impulses of the individual as the fundamental factor in the formation of the super-ego we do not deny the importance of the objects themselves for this process, but we view it in a different light." Now it may be pointed out that in emphasizing the importance of the external objects in the formation of the super-ego, the role of the innate impulses of the individual has not been denied. The question at issue is whether the ethical beliefs which form part of the super-ego are injected into the individual apart from and independently of his experience of the material world, or whether they are formed by the interaction of the personality and the world; there cannot be any question of the super-ego being impressed by external circumstances on to a merely receptive and featureless individual. The answer which I am urging is that the situation is actually parallel to that with which we are familiar in genetics; all characters are, as Goodrich put it, both inherited and acquired; they are products of the interaction between the genes, which we usually consider internal, and the equally necessary factors, such as oxygen, nourishment, etc., which we usually consider external. Strictly speaking, one cannot say that the propositions of ethics arise from experience of external, as opposed to internal, connexions; their origin is the observation that the world is such, and the personality is such, that the individual must follow certain rules.

Here, it may be urged, the word "must" in the last sentence may be going too far. Granted that the propositions of ethics are derived from experience, does that experience teach us more than techniques which lead to pleasurable results, and do we still need to invoke some non-experimental criterion to judge, not what gives us pleasure, but what *is* pleasurable or good and what bad? But if there were any such ulterior criterion, it would have to be of the most general and unspecific character. What we are considering is not the abstract entity 'ethics', but actual super-egos as they are effective in human personalities; and they are so variable from person to person, that, if their contents are taken to consist of rules for obtaining some ultimate objective, that objective must be of an extremely vague character. Further, there are many propositions for which it is clear that no ulterior criterion of value is necessary. The statement that it is as well not to put your hand in

the fire is not based on anything else except the fact that if you do it will cease to be a hand: and existence is its own justification; hands are the kind of things which do not go in fires. Self-destruction of an entity only comes into question when there also exists some large unit of which that entity is a part, and it only occurs when this more inclusive unit is more powerfully energized in the dynamic system of the super-ego.

According to some psycho-analysts, an urge towards self-destruction is, in actual fact, very early awoken in the young child. But there is obviously in existence an entity in which the child is only a part, namely society, and the facts which the child is learning and incorporating into its super-ego are very largely facts about the existence of society and his place in it. He discovers, for example, that if, in anger at being denied the maternal breast, he attempts to attack his mother, he is either restrained or at least disapproved of. That disapproval is ultimately based on nothing more than the existence of society, which would be impossible if aggression were uncontrolled. The child, of course, does not himself discover that the existence of the society of which he will be a member demands the control of aggression; that knowledge can only belong to his parents, and may not be formulated even in them. But the disapproval which the child experiences is a result, mediated either by intelligent knowledge or by the unconscious processes of natural selection, of the requirements of human society. The ethical principle 'Be good, sweet child!' derives what validity it has from social facts as real as the calorie quota for human survival.

During the very early months, when the main structure of the super-ego is being formed, the most important facts which come to the notice of the child are social facts, arising from its relations with its parents, nurse, etc. The anthropological discovery that systems of ethics differ in different cultures is therefore not only not surprising, but is indeed a necessary consequence, and a confirmation, of the view here put forward. The way in which these systems of social behaviour are conditions for the existence of the cultures concerned has been fully discussed by Malinowski and his followers. But we must, I think, go farther than this. Ethics, at this point in the argument, appears as a system of rules of action derived from the necessary conditions for the existence of society. They appear, that is to say, as simply conservative. It would be a sanguine man who would depreciate such a function at the present day, but we cannot in fact expect society to continue unaltered. A tendency to evolutionary or developmental change is a general characteristic of biological entities, including societies, and it is certainly true of Western European civilization that the ethical systems engendered within it are not simply conservative but are among the agents of this change.

The contribution which theoretical Marxism made to the study of ethics was actually not to debase ethics to the position of a mere epiphenomenon, but was a combination of this point with the anthropological argument mentioned above. The widespread misunderstanding of this is partly due to the very diverse, and sometimes regrettable, practical applications of the Marxist theses on ethics which have been made by various political parties; and partly to a certain naughty-boyishness, a roguish delight in paradox *pour épater les bourgeois*, in the Grand Old Men themselves. Such a spirit is perhaps not unexpected in professional revolutionaries, but it has led to some remarkable confusions when interpreted by the more earnest of the true believers.

Marx and Engels urged, first, that ethical ideas are derived from the experience of social facts. This part of their argument is one of the almost innumerable meanings of the famous phrase 'freedom is the knowledge of necessity', an epigrammatic statement the highly complex ambiguity of which should commend it to the school of poetic criticism represented by Mr. Empson. Further, they asserted that different social classes, encountering different material conditions, form different ethical systems. They also showed that the differing conditions of the social classes bring about developmental changes of the society as a whole. Since they, of course, acknowledge the fact that "all the driving forces of the actions of any individual person must pass through his brain, and transform themselves into motives of his will in order to set him into action"[7], this implies that it is only through the systems of beliefs to which they give rise that the social conditions are effective. The point was somewhat obscured by their insistence on what was the newest and most controversial aspect of their doctrine, namely, that the social facts from which the ethical systems are derived could be ultimately reduced entirely to matters of economics. And it was, as mentioned above, also concealed by some of their more irresponsible utterances; for example, by Engels: "it is precisely the wicked passions of man—greed and lust for power—which, since the emergence of class antagonisms, serve as levers of historical development"[8], in which he emphasizes the imperativeness of the socially determined Good by comparing it to unrestrained biological drives. But, in spite of the confusion caused by such verbal tricks, Marxism did provide the logical basis for the view that realist ethics can change society and not merely preserve it.

Having now reached the position of seeing a social system as something the existence of which essentially involves motion along an evolutionary path, we are confronted again with the question which was discussed five paragraphs above in terms of static existence: Do we need some external criterion to decide what is the 'good' direction of evolution, or is that implicit in the society? Again, I think, one can answer that no criterion external to the natural world is required. An existence which is essentially evolutionary is itself the justification for an evolution towards a more comprehensive existence; a society implies a direction of development into a society which could include the earlier stage, as, to take an exaggerated example, American culture can include that of the Red Indian, but not vice versa. One can put the same thing in another way by reference to the history of evolution; on the whole, the later products of animal evolution have capacities which include and transcend those of their ancestors.

But, it may be said, granted that the existence of a society does imply a direction of change, why should that direction be accepted as good? One could quote eminent authority against such a view. "Let us understand, once for all," wrote T. H. Huxley[9], "that the ethical progress of society depends, not on imitating the cosmic process, still less in running away from it, but in combating it." But he was writing under the spell of that extraordinary impulsion, so incomprehensible to us to-day, which forced the Victorians to transmute the simple mathematics of their major contribution to theoretical biology into a battle-ground for their sadism. To Huxley, the cosmic process was summed up in its method; and its method was "the gladiatorial theory of existence" in which "the strongest, the most self-assertive tend to tread down the weaker", it demanded "ruthless self-assertion", the "thrusting aside, or treading down of all competitors". To us that method is one which, among animals, turns on the actuarial expectation of female offspring from different female individuals, a concept as unemotional as a definite integral; and we can recognize that quite other, though equally natural, methods of evolution may occur when it is societies and not individuals which are in question. Moreover, being no longer hypnotized by the methods of evolution, we can see its results; and they cannot be adequately summarized as an increase in bloodiness, fierceness and self-assertion.

Huxley, in fact, was morally outraged by what he took to be the character of the cosmic process, and was therefore forced to exhort civilization to combat it. With our present ideas, the general character of the cosmic process, or as we should now say, of the course of evolution, does not seem so morally offensive that we cannot accept it. To return to our question, we must accept the direction of evolution as good simply because it *is* good according to any realist definition of that concept. We defined ethical principles as actual psychological compulsions derived from the experience of the nature of society; we stated that the nature of society is such that, in general, it develops in a certain direction; then the ethical principles which mediate the motion in that direction are in fact those adopted by that society. Of course the good is, as the anthropologists pointed out, different in different societies, and particular cultures which regress may be actuated by principles at variance with the cosmic process. But in the world as a whole, the real good cannot be other than that which has been effective, namely that which is exemplified in the course of evolution. It should be noted that this, if you will, cosmic fatalism, does not imply a fatalistic attitude to the evolution of any particular section of the world, for example, of the society of which one happens to be a member.

It is, then, finally clear that science is in a position to make a contribution to ethics, since ethics is based on facts of the kind with which science deals. And the nature of science's contribution is also clear; it is the revelation of the nature of the character and direction of the evolutionary process in the world as a whole, and the elucidation of the consequences, in relation to that direction, of various courses of human action.

But the practical difficulty remains. The fundamental features of an ethical system are formed, as part of the super-ego, in the very early years of life. A child learns at its mother's knee that aggression must be controlled; and it learns a very little later that taunting its younger brother's weakness is a form of aggression; but when does it learn that adopting an unscientific attitude to the social problem of nutrition is also aggression? Most of the scientific contributions to ethical thought are of a kind which seem, at the present time, difficult to convey in the early formative years in which the most effective features of the super-ego are being laid down. Perhaps this appearance is deceptive, and perhaps after a few generations the fundamental notions of the scientific outlook will be so deeply incorporated into normal life that they can be transmitted by the unconscious gestures of mothers and nurses. An adequate psycho-analytical study of people who have grown up in Soviet nurseries might tell us whether this is too wildly optimistic. But in any event we should do well not to neglect the second line of attack, but should study deeply how the intellectual content of the super-ego may be modified in later life, and the data which we can provide about the nature of the cosmic process

appropriately attached to the powerful general principles about love and aggression which are by that time already in existence. It is the profoundest of scientific principles that a theory must work in practice; and that applies to scientific ethics no less than to the latest modification of the quantum theory.

I FIND myself in fundamental agreement with Dr. Waddington, though I should base my argument on an epistemology more explicit than his own. To start off, I would aver, with Mach, that "bodies or things are compendious mental symbols for groups of sensations—symbols that do not exist outside of thought". The basis of all knowledge is experience. So-called external objects are constructs from experience: equally the doctrine of evolution and the view of the universe summed up in the Ten Commandments are constructs from experience. Of course, the experience may be partial: elements in it may be false (that is to say, unconfirmed by the majority of our fellowmen). The activity of the mind which links together elementary perceptions and fashions the constructed symbol may be inadequate to make a symbol which shall cohere with other symbols as we try to picture some wide region of the universe in which we find ourselves. But by a process of trial and error, in which the individual constantly checks his experience by that of others, the race has gradually created, among other ideas, those which we distinguish as external objects, laws of Nature and ethical principles.

We assume that there is an external world of objects to which our bodies belong. But, if that world exists, is our picture of it correct? We cannot say, for we cannot transcend human limitations. Are our scientific laws accurate? Probably not: they correspond, however, to humanity's present state of mental development. Can we say that our ethical standards and the commands by which we seek to make them effective are sound? They, too, are as partial, as transitory, as our supposed knowledge of the spiritual character of the universe.

Are then our scientific laws and our ethical principles of no value? By no means. They are approximations to truth, nearer than those which were reached in the past and later modified or even discarded by the growing wisdom of the race.

Unfortunately, the problem of the mind-body relation is so intractable that it is difficult to say how far intellectual and ethical tendencies are inherited. I would agree with Dr. Waddington in affirming Goodrich's conclusion that all characters are both inherited and acquired. The genes carry certain modes of reaction to environment. A relatively homogeneous community is built of the same stock of genes changed to some extent by recurring mutations; and an individual born into it assimilates with especial ease the community's intellectual, social and ethical formulation of experience.

Is Dr. Waddington quite fair in his strictures of T. H. Huxley? The evolutionary process on earth, until the rise of the placental mammals with their increasing parental affection, was non-moral. "Nature red in tooth and claw" is an actual fact. Huxley was right in asserting that between man and the cosmic process as it has been, there ought to be war. The strongest objection to ethical theism lies in the fact that the creative process has been non-moral. But just as evolution has been a creative process in that new things, and in particular man himself, have emerged in it, so it may well be that the process itself is being transformed: no longer, it may be, are new animal forms being evolved, but new levels of spiritual understanding are emerging. Boutroux died twenty years ago, but his "Religion and Science in Contemporary Philosophy" is not out of date. He said: "According to the results of science herself, there is nothing to guarantee the absolute stability of even the most general laws that man has been able to discover. Nature evolves, perhaps even fundamentally." He added that, if the remotest principles of things are thus transformed, that very transformation must obey laws which are analogous to the immediately observable laws of experiment. Are we wrong behind such change to find purposive activity, to postulate God as its source, and to see in the ethical change which results from the growth of human experience His progressive revelation of Himself?

E. W. BIRMINGHAM.

Bishop's Croft,
Birmingham.

COMMENT on Dr. Waddington's important and interesting paper is difficult because it raises so many questions which are highly controversial. Only a treatise could deal with them all. I must confine myself to some rather disconnected jottings. Frankly, I am not quite clear about the main

thesis. If it is that the natural sciences have a valuable contribution to make to the study of ethics, few would deny it ; if it is, as I think, the contention that the central problem for ethics can be solved by the method of natural science, that seems to me a disastrous error. No doubt science can throw light on the way in which minds come to apprehend values but, as it seems to me, it cannot determine whether they are truly values or only appear to be such, nor can it determine the scale of values, if any.

A certain scepticism about some of the alleged findings of science may be permitted. For example, the super-ego appears to me to be a piece of useful mythology ; probably it helps to "explain" the process by which we reach ethical maturity, but may it not be misleading to treat it as an "entity" ? The important fact is that mature and sane men have ideals which, as they believe, commend themselves to their reason, and sometimes they have imaginary pictures of themselves as they know they ought to be. Again, the diversity of moral codes at different levels of civilization can be exaggerated. Virtues which are honoured among us, such as courage or even kindness, are honoured in crude and more limited forms by people of lower cultures. The development of moral ideas is not determined wholly by social condition ; there is a dialectical development of the ideas themselves, and if it is true to say that societies create ideas, it is even more true to say that ideas create societies.

The use made of the psychological concept of "compulsions" perplexes me. As I understand it, a compulsion is an irrational and perhaps irresistible tendency arising from the unconscious. The moral experience in its authentic form is surely the opposite of a compulsion. The agent believes himself to have the responsibility of choice and the ethical "ought" is recognized not as something which must be obeyed but something which deserves to be obeyed, though it may be difficult and unpleasant. "Had it power (compulsion) as it has authority, it would absolutely rule the world." I am even more perplexed by what seems to be asserted about the goodness of evolution or even of all existence. "We must accept the direction of evolution as good simply because it *is* good." I think I must have failed to grasp this point, because in the preceding sentence we are told that revised ideas about evolution enable us to feel that it is not morally offensive, as T. H. Huxley thought it was. This seems to imply that Dr. Waddington has considered the course of evolution and found that it is not morally offensive. Now, how, on his own principle, could he possibly do that ? What criterion did he apply ? No doubt, as a theist I am bound to hold that there is a direction in evolution or rather that organic evolution is a part, perhaps a very small part, of the Divine purpose, but I see no reason to suppose that at any given moment the actual direction of evolution is towards higher values, and this is pre-eminently the case when the process is largely determined by human will.

There is a most fundamental problem raised for ethics by the evolutionary hypothesis. I wish that Dr. Waddington had said more about it. Shortly it is this : evolution appears to suggest that all moral ideas are relative, but the moral consciousness regards some of them as absolute and unless it does so the moral life is simply abolished. We are confronted with the situation now in every home. There are some things of such value that men ought to be prepared to die for them ; it is reasonable to be prepared to die for them. Why ? Men answer with action and, it may be suspected, deplorably confused notions of ethical theory ; but they act because, in their simple way, they believe that the voice of duty comes from a Source deeper and more intimate than the course of evolution.

W. R. MATTHEWS.

The Deanery,
St. Paul's,
London.

I JOIN issue with Dr. Waddington on two points. First, when he offers, as a typical example of a judgment that is at once ethical and scientific, the statement "You are an animal of such a kind that you must consume 7 mgm. of vitamin C per diem, and should consume 10 mgm.". I see nothing ethical here at all. The rules acquire ethical significance only when in a given case I judge the effort after survival, to which it prescribes the means, to be morally right or wrong. If I am the father of a family and there is only a limited supply of vitamin C available, it may be my moral duty to throw the rule to the winds and forego the means to my survival. The 'must' of the rule is not the unconditional 'ought' of morality, but the condition of attaining an end, as to the morality of which the rule says nothing. The 'should' in the last clause is ambiguous ; it may mean either 'you ought to' or merely 'you will have a better chance of surviving if you do'. The former meaning alone is ethical, but I fancy that Dr. Waddington intends the latter. He may reply that he sees no difference between the two, any more than when on a later page he identifies what is pleasurable or what leads to pleasurable results (two different matters, by the way) with what is good. We seem to be back in the dear old days of Herbert Spencer. Do fallacies never die, however often they are confuted ? If 'you ought' is identical with 'you'd jolly well better', and if 'this is good' is only another way of saying 'I find this pleasant', then the moral consciousness

is an illusion and a cheat, and the sooner we stop talking about it the better.

Dr. Waddington puzzles me, again, when he argues that the evolutionary process itself supplies us with a criterion of good, and that we need no other. I fail to see what he means by saying that this "cosmic fatalism does not imply a fatalistic attitude in the evolution of any particular section of the world", for example, of one's existing society. The 'psychological compulsions' with which he identifies ethical principles are surely, in his view, determinant of every act of every citizen in every race and age. If so, morals, whose business it is precisely to draw 'class-distinctions' among our natural impulses, vanish from the picture. Moreover, what ethical criterion can be derived from the scientific doctrine of evolution? Biology knows nothing of the qualitative distinction of higher and lower, better and worse; it can only display the continuity in the modifications of species through descent, showing what form of life succeeds what, and that certain more complex organisms have less complex organisms as their temporal antecedents. If the second law of thermodynamics should work its will and if all mind and all life should be eliminated from our planet, the process would be just as much an evolutionary process, in the sense relevant to biology, as that by which man has arisen from the ape. Apart from ethical presuppositions read in from other and non-scientific sources, evolution has no concern with value. The cosmic process is not indeed, as Huxley thought, immoral, save for those who indulge the 'pathetic fallacy' and interpret it in the light of their own emotions; but it is wholly amoral. The scientific study of it cannot teach us what is good or what we ought to do. It cannot even say 'must' in its predictions; it can tell us only what has been, what is, and what, in varying measure of probability, will be in the time to come. It cannot tell us that what will be is right or good.

These are my two grounds of dissent from Dr. Waddington, and I think they are fundamental to the issue. With much else in his article I cordially agree. But I venture to add a remark that travels a little beyond the scope of his discussion. It seems to me important to grasp the bearings of this amorality of Nature on our present world troubles. Are they not in large measure due to the fact that our knowledge of science, especially in its practical applications, has outrun, far outrun, our morality? Science has placed instruments of world-shaking power in the hands of rulers who abuse them for their own unrighteous ends. These instruments are in themselves, like physical Nature, non-moral. Neither Nature nor science is to blame for their misuse by man. Morality lies in the will to good, immorality in the will to evil, that is, in the choice of ends, not in the means to their attainment. Of those ends, whether they be good or whether they be evil, science, for all its glory, can tell us nothing.

W. G. DE BURGH.

Little Cocklands,
Burford, Oxon.

I PROPOSE to touch very briefly on those points in Dr. Waddington's article with which I agree, although, even where I agree, I cannot resist the temptation of entering a disclaimer against his uncritical taking over lock, stock and barrel of the pretentious jargon with which psycho-analysts disguise the commonplaceness of their observations upon the obvious. What, for example, does all this talk about the super-ego and its imposition upon the personality—is it, for example, upon "a merely receptive and featureless individual" or upon one who is "himself a factor in the origin of his super-ego"?—really amount to? That there is an individual person exhibiting certain specific characteristics which distinguish him from others—my dislike, for example, of the taste of marzipan, or my delight in the smell of privet; that this individual is born and grows up in an environment and that his resultant beliefs, including his ethical beliefs, are the result of the impact of the environment upon the characteristics which distinguish him from others, as well as upon those which he shares with others. That, as it seems to me, is all that Dr. Waddington and Melanie Klein are saying, and, put like that, it scarcely seems to justify the fuss.

I agree again with Dr. Waddington's interpretation of Marxism. I agree, that is to say, that Marx *did* provide for changes in, as well as conservation of systems of, social ethics, while retaining my private opinion that the real agents of ethical change are to be found less in the factors that Marx and Dr. Waddington emphasize than in the appearance of an ethical 'sport' in the shape of a Christ, a Buddha, a Socrates or a Blake who points the way to new levels of conduct and new standards of value to which in course of time the accepted moral codes of society as a whole gradually creep up. Or don't creep up! If they don't, then, to adopt a biological metaphor, the 'sport' has failed to breed true. I deliberately employ the biological metaphor in witness to my belief that the process of evolution still proceeds by 'mutation', although the scene of its operations has now been largely transferred from the physical to the mental and spiritual spheres.

So much having been said by way of not very impressive agreement, I come to my two major quarrels.

About the first I must say very little, not because it is not important but because it is subsidiary to Dr. Waddington's main thesis. He says that, if the contents of super-egos are taken to consist of general rules, they must be rules "of an extremely vague character". In more familiar language, the deliverances of men's moral consciousnesses vary so much that no general ethical principles as to what is good and right can be laid down.

I deny it, and claim that we do in fact all know, and always have known, that unselfishness is better than selfishness, kindness than cruelty. What is more, we can all recognize a case of cruelty when we see it and know that we ought to try and stop it—(the fact that we usually do not try is not to the point). I should go further and maintain that we do all of us know the sort of way in which we ought to live; that we know, in fact, that we ought to live very much as Christ enjoined. We may say that Christ's prescription for good living is wholly impracticable or is much too difficult; but that does not alter our conviction that it is the right prescription. The difficulty about ethics is not that we don't know what is right and know with a good deal of particularity, but that we lack the will or the ability to act in accordance with our knowledge.

Secondly, on Dr. Waddington's main point, I cannot understand how anything can be measured without a ruler which is external to and other than what it measures. Now to adjudge a movement as good or as bad—witness in this connexion Dr. Waddington's talk about "the 'good' direction of evolution"—entails that some meaning is understood to be conveyed by the words good and bad which serves as a standard of measurement by reference to which the movement is evaluated. Now this meaning cannot itself be part of the process which it is invoked to evaluate, any more than a ruler can be part of the length which it measures, or a man can lift himself by his own braces. Dr. Waddington points out that later stages of evolutionary development include the earlier. Certainly they do, but what of it? The later stages of a travelling snowball include the earlier, but that does not mean that the snowball's journey is ethically valuable or worthy of praise. It may not even be well advised; if it is heading for a precipice it is ill advised. The point is surely obvious enough. When Dr. Waddington affirms that evolution is moving in the right direction or is progressive—it is "good", he says, "simply because it *is* good"—he is applying ethical standards to it. Now all progress implies movement in a direction and direction implies a goal. If I put myself in the Strand and set my legs in motion, there is movement or process, but until I know whether I want to go to Charing Cross or Temple Bar I cannot say whether I am progressing or not. But the goal cannot be part of the process which seeks to realize it.

Once this is understood, it will be seen that the kind of question which Dr. Waddington is putting, when he applies the notion of 'right direction' to evolution and then proceeds to inquire whether our present direction is "right", is, *if we are to proceed on his premises*, like the question "Is it better to take the right fork or the left?" when asked by somebody who does not know where he wants to go; while further questions relating to the speed of the advance are like asking whether it is better to travel in a 40- or a 10-h.p. car, when you don't know where you are travelling, or whether it is good to travel at all.

C. E. M. JOAD.

Birkbeck College.

IN commenting upon Dr. Waddington's article, the need to be brief compels me to concentrate upon a single point and to say too shortly what requires to be argued with the help of detailed examples. The point I select for comment is that the contribution of science to ethics lies in its revelation of "the character and direction of the evolutionary process in the world as a whole", and that the examination of this direction will yield the criterion of human action. Although I am in agreement with much that Dr. Waddington says here and in his little book, "The Scientific Attitude", I find a serious difficulty in understanding his present argument. He maintains that the "real good" is that which has been effective, that is, that which has been exemplified in the course of evolution; accordingly, he argues that "we must accept the direction of evolution as good simply because it *is* good according to any realist definition of that concept". Presumably the word "must" in this sentence means "are logically compelled", so that our acceptance is an admission of what follows logically from the "realist definition" of good.

It is not, however, clear whether this is what Dr. Waddington means since he at once proceeds to drag in the notion of fatalism, in order to ward off a possible charge of being fatalistic. But such a charge would not make sense if I have correctly interpreted the phrase "we must accept". The difficulty is increased when we take note of the context in which the sentence I have quoted occurs. Dr. Waddington is disagreeing with T. H. Huxley's protest against accepting the cosmic process as the standard of ethical progress. The answer he makes consists of three parts, or—as I prefer to put it—he gives three different answers: (1) the method of evolution is to us—as contrasted with Huxley—"as unemotional as a definite integral";

(2) the results of evolution cannot be adequately summarized as an increase in bloodiness, etc.; (3) the course of evolution does not seem to us now "so morally offensive that we cannot accept it". But (3) seems to me to make a muddle of the argument. If good is defined as that which is effective, that is, that which is in the direction of evolution, what is the point of answer (2)? And if the concept upon which the method of evolution turns is unemotional, then why, again, bring in (2)? In short, it is not compatible with Dr. Waddington's "realist definition" of "good" to speak of the course of evolution as morally offensive or morally admirable. But his answer (2) suggests that he does think it necessary to show that Huxley was mistaken in his estimate of the blood-thirsty character of the struggle for existence. Suppose Huxley's estimate had been correct: would it make sense to say that the evolutionary process was morally offensive?

L. SUSAN STEBBING.

Bedford College,
London.

I HAVE read with great interest Dr. Waddington's lucid and well-reasoned essay in speculative metaphysics, into which he has ingeniously woven hypotheses derived from Freud and Marx, but I fail to see the alleged connexion between science and ethics. He says that the contribution of science to ethics is "the revelation of the nature of the character and direction of the evolutionary process in the world as a whole, and the elucidation of the consequences, in relation to that direction, of various courses of human action". (This might almost be a quotation from Herbert Spencer.) The direction of the evolutionary process may have been revealed to Spencer or Dr. Waddington, but not by science. It is said that Amœba and Hydra represent early stages in animal evolution, yet there are plenty of them alive still. For all we know they may survive long after Homo has perished by mutual slaughter. Would that make them better or worse from the scientific point of view?

The process of evolution has thrown up Hitler, Himmler, Goebbels and their like. If they were to win the War, would that show the direction of the evolutionary process? Evolution has produced the nightingale and the kingfisher we admire; also Sacculina, the parasite of the common shore crab, and also the matrimonial habits of spiders, which we do not admire. Does science tell us which is better? I select these examples because they are of no evident economic importance and our judgments may be considered disinterested. I am not arguing that these judgments of approval or disapproval are subjective or irrational, only that they are outside the scope of science. By reason of its method the only values within its scope are truth and error as judged by logical consistency and conformity to fact. If the logical positivists confined themselves to this assertion they would be on safe ground. I am not arguing, either, that Dr. Waddington's theory is wrong, only that, like every ethical theory (including the theory that there are no ethical distinctions or that they are meaningless), it rests on *a priori* presuppositions it is best to be honest about.

On a minor point, I must protest against the notion that it is a recent discovery that different societies have different moral codes. It seems to have been known to the author of the "Odyssey", and certainly to Herodotus a few centuries later. Lastly, may I recommend Dr. Waddington (and others interested in the relations of science and ethics) to read "Five Types of Ethical Theory" by Prof. C. D. Broad, where he will find his own type of theory labelled and docketted; and specially to read p. 284—the last page but one?

A. D. RITCHIE.

University of Manchester.

MUCH appreciation is no doubt widely felt for Dr. Waddington's statement that, if various modern theses are correctly interpreted, ethical judgments are allowed by them to be "statements of the same kind as scientific statements". One also agrees with his view that the putting forward of these theses has somehow persuaded many people of a lack of any link between science and ethical systems. This seems a natural temporary reaction belonging to what Samuel Alexander called the deanthropizing phase of thought. For millennia, men have sought authority for social codes in anthropomorphs created by their imagination outside the evolutionary sequence and empowered to insert into it new items—dispensations they have been called—from time to time. The comparative method in the study of man, outstandingly represented by Frazer, has vividly suggested that what were held to be impregnable rock-fortresses of traditional belief are, rather, erratics in the moraines of folk-lore. The old authority has gone. It withered too, at a time when an individualist age was obsessed with the idea of Nature red in tooth and claw, and even a Huxley could suggest that men's ethical systems must stand in antagonism to the cosmic process.

In their various ways Alexander, Lloyd Morgan, Smuts and Sherrington are trying to get us beyond the inevitable phase of disorientation. Unlike older systems, the work of science must not claim to give us something complete and unchanging;

it must have ever-recurring readjustment as its key note. Would that those who are busy making blue-prints of a better world would realize this; so many of their schemes are static! Perhaps a main contribution of the humanist at the present juncture is the thought that man is a social being, and that, within society, there is an unceasing and not always successful struggle towards freedom of conscience, towards replacement of external by internal factors. One may add that the survival-value of this freedom is related to the facts of observation and inference, namely that life's history on earth has been a process of ever-recurring readjustments, and that, with few exceptions, the fate of those forms which did not readjust has been extinction. At the same time, it should be remembered that these developmental adjustments are selective; if some features are enhanced, others are atrophied. So it is not very wise to suggest that the later include the earlier; that unduly simplifies the idea of change and suggests acceptance of the rather crude notion of the inevitability of progress.

H. J. FLEURE.

University of Manchester.

OUT of the breakdown of traditional systems of thought, glimmers of new light appear, islands of solid land emerge out of the chaotic flood. Dropping metaphor, the question is whether any new system of thought, sufficiently strong to provide the foundation for living, can be evolved in time to substitute reintegration for disintegration. As science has played a major part in bringing about the disintegration of the old, it should attempt to do at least as much in the new integration.

Dr. Waddington's interesting article is a valuable contribution to this. As he points out, psychology, anthropology and sociology have largely contributed to the breakdown of traditional views on ethics. He might have added many other sciences. Evolutionary biology is one, with all its implications as to human ancestry, the struggle for existence, and the abolition of the idea of purpose in evolution. All the physical sciences have contributed, by providing a mechanistic explanation of natural phenomena previously attributed to supernatural powers and often invested with an ethical aura—witness the legend of the rainbow in the Old Testament, or the frequent view of lightning, floods or earthquakes as expressions of Divine anger. Similarly, physiology and pathology have removed deformity and infectious disease from the ethical sphere; they are no longer considered as Divine retribution for moral lapses.

When it comes to the constructive side, I have little to add to Dr. Waddington's interesting thesis. He might, I think, have pointed out that in some cases science indicates a new ethic, or at least a new type of ethical approach to old problems. This may be illustrated by my last example. We can no longer believe that pestilence has any connexion with moral lapses in the conventional sense, or with the failure to observe certain rituals or to believe certain dogmas; but we can lay down certain new types of moral duty arising out of the nature of infection—duties both individual and social, concerning cleanliness and the prevention of disease and of its spread.

I have two specific comments. One concerns the basis for the quality of absoluteness and other-worldliness possessed by the super-ego and the systems of ethics for which it is the vehicle. Dr. Waddington makes what I believe to be the quite novel suggestion that this is connected with the breakdown of the solipsistic early phase of the child's existence. While this may be a contributory cause of the other-worldliness, I cannot feel that it accounts for the absoluteness, for the fact that certain aspects of morality are felt as a categorical imperative. The origin of this, as I have elsewhere suggested, must more probably be sought in the all-or-nothing method adopted in higher animals for avoiding conflict. This has been proved to operate to prevent conflict between antagonistic muscles and between competing reflexes. Observation shows that it must also normally apply to competing instincts in sub-human vertebrates. Finally, all we know of human psychology indicates the strong probability that it operates in repression in early life. Man is the only organism in which conflict is normal and habitual, so that some form for minimizing its effects is essential; and this will be of the greatest importance in early childhood, before sufficient experience has been accumulated to enable conflict to be dealt with empirically and rationally.

The antagonistic forces which hold down repressed ideas and impulses are kept away from the main body of consciousness; hence the apparent externality of ethical law. They are held there by the strong but automatic processes of repression; hence the compulsiveness of the super-ego. And repression is, or attempts to be, total, seeking to keep certain impulses wholly out of consciousness; hence the all-or-nothing character of the ethical prohibitions of the super-ego.

Some repressions are more complete than others; and in many cases the degree and method of repression can be modified or the prohibitions of the super-ego transferred in their operations from one field to another. Hence we may say that a great part of our ethical development will consist in diminishing the absoluteness and compulsive-

ness of our early categorical imperatives, and in altering the field to which they apply, in the light of reason and experience.

Put in another way, we may say that primitive and absolutist ethics, based on the non-rational and unconscious processes of the mind, inevitably tend to limit human activity by locking up conflicting psychological 'energies' in the repressive mechanism of the unconscious. For constructive and truly humanistic ethics, we need to liberate these forces from their unconscious grappling, through reason and still more by appropriate education and by opportunities for fuller living.

The other point which I would like to make is perhaps even more fundamental. Dr. Waddington writes: "an existence which is essentially evolutionary is itself the justification for an evolution towards a more comprehensive existence". While this is true, it is so general as to smack of Panglossic optimism. It is an observed fact that the majority of evolutionary trends are either irrelevant to progressive change, or are even opposed to it in direction, or are inherently limited specializations. As I have set out at some length elsewhere (in the first essay in my book "The Uniqueness of Man") evolutionary progress can be objectively defined, and further is a rare phenomenon; the potentialities of further true progress now appear to be restricted to our own species, though there is no guarantee that we shall achieve them. The problem here is thus to study the possible directions of change; to decide which make for progress and which do not; which make for unlimited and which for limited progress; and to attempt to adjust our social systems and our ethical ideas in such a way that, as Dr. Waddington rightly points out is possible, they should form a mutually reinforcing whole, making for the maximum speed of progress in the correct direction.

Dr. Waddington points out the difficulties arising from the fact that the ethical systems of different societies differ enormously, one conception of the good often contradicting another. Here again there is an evolutionary parallel. Thanks to the work of Sewall Wright, we know that small and isolated animal and plant species will often show 'accidental' differentiation, which is not necessarily biologically advantageous, and may sometimes even be disadvantageous. The same appears to apply to the evolution of cultures.

Further, as Darlington has pointed out in his recent book, "The Evolution of Genetic Systems", certain evolutionary changes may be of immediate advantage, but of eventual disadvantage in robbing the stock of evolutionary plasticity and adaptability. Here again there are doubtless parallels from ethics. The short-term efficiency of ruthless State dictatorship as opposed to the inevitable long-term triumph of more humanistic systems is a case in point.

With such modifications, Dr. Waddington's thesis of ethical systems as indispensable social organs, derived from the impact of a changing external world on the minds of individuals via the social environment, but themselves then helping to effect changes in the external world and the social environment, appears to be a fundamental one, and worthy of the most careful study.

JULIAN S. HUXLEY.
Zoological Society of London.

SCIENCE AND MARXIST PHILOSOPHY

IT is a little more than ten years since the London Congress on the History of Science. It was there that the Soviet delegation first brought effectively to the notice of British men of science the contributions that Marxist thought had to make to the natural and social sciences. The symposium organized by Marx House held during August 16–17 has served to show that there is now a widespread and growing interest in this development, and that we are clearly on the way towards a more profound and comprehensive appreciation of science as a human social activity. The two days sessions of the symposium had as keynotes two of Engels' works, "The Dialectics of Nature" and "The Origin of the Family", illustrative of the scientific and sociological aspects of his work.

The first was introduced by Prof. H. Levy, who discussed the changes that the present century has brought about in the attitudes towards philosophy and science, contrasting the older tendencies towards pure science cultivated for its own sake with those of a planned science in the service of the community. He showed how the former tendency is working itself out in the direction of the claims of *a priori* knowledge, as evidenced in the recent discussion in NATURE between Jeans and Eddington. The majority of men of science, however, are coming more and more to see their activity as part of social enterprise, and to realize that science represents the achievement of human action in an infinite field of ignorance; indeed, that in a sense, the man of science creates new ignorance with every problem he solves. The old absolute views of knowledge and logic are giving way to one in which probability has a much greater part. We need for the advancement of

science a philosophy that will take all these tendencies into account; and the basis of that philosophy has been laid by Marx and Engels.

Dr. J. Needham provided an interesting analysis of Prof. Whitehead's philosophic opinions. Although Whitehead probably never read Marx, he was led, in attempting to achieve a unitary view of biological and physical phenomena, to an attitude essentially similar to that of the dialectical materialists. In his insistence on the close relation between succession in time and a series of envelopes in space, Whitehead developed a hierarchical series of organizations passing from the purely physical structures of atoms to those of animals, and ultimately societies. Whitehead failed, however, according to Needham, to push his arguments to any practical conclusions, not seeing that any further stages in organization were yet to come.

Prof. J. B. S. Haldane took up the question of the development of science since the writing of "Dialectics of Nature". In that book Engels stressed the chief scientific discoveries—notably the law of the conservation of energy and the theory of evolution—that led to the breakdown of the older and essentially static views of the universe. Haldane carried the analysis on through the achievements of present-day science. He laid particular stress on the fact that the breakdown of boundaries between the different sciences has progressed much further than in Engels' time. The development of modern physics, with its fundamentally dual aspects of wave and particle, fits in particularly well with the dialectical picture that Engels developed. Recent cosmological research has shown that even the laws of physics cannot be taken as fixed and unalterable, but are only so in relation to our very limited experience of time. Everywhere, the picture of the universe as a series of transformations brought about by internal instabilities is gaining ground. The great developments of biochemistry and genetics are providing new links in the chain that joins the inorganic and the organic worlds.

The second day of the symposium was devoted to social and anthropological subjects. Here, as in the natural sciences, a remarkable change has come about in the last few years. Emphasis on the importance of social and economic conditions in anthropological and historical studies has become almost universal. Prof. G. Thomson in his introductory paper provided a brilliant study of that neglected nineteenth-century pioneer, Morgan, the virtual discoverer of the universal form of society, based on clan organization and matrilinear succession, that has preceded our own individualist family organization. Engels took up Morgan enthusiastically in his "Origin of the Family", but more recent anthropological work seems to discredit many of Morgan's conclusions. Prof. Thomson discussed these criticisms in the light of the most modern evidence, and showed that though Morgan's view is necessarily limited by the comparatively undeveloped anthropology of his time, his main conclusions have only been confirmed and enlarged. Similarly in physical science, the reaction against the disturbing character of these views led to a sheer obscurantism and the denial of any principles in history or in social development.

Dr. Barbara Ruhemann discussed the economic origins of the universal totemism that accompanies the clan family organization, and further discussion on this subject was provided by papers by Mr. Lionel Naftalin on the relations between slavery and feudalism, and by Prof. Pascal on the *gens* in primitive Germanic society. All these went to show how rich a clue to the study of social origins is furnished by the work of Morgan and Engels.

The new unification of the sciences and humanities was brought out in a striking way in two papers on medicine presented by Prof. B. Farrington and Dr. Ruscoe Clarke, on the subject of the social significance of medicine in early times, and at the present day. Prof. Farrington traced the way in which medical practice has turned from primitive social health service embodied in practical healing lore to a pretentious and specialized medical practice for the benefit of the rich: showing how the emergence of a leisured class has distorted the development of medicine. He pointed out how from the period of the rise of the Greek City State to the eighteenth-century enlightenment, medicine consistently neglected a study of the diseases afflicting the common people, and even more of the special diseases which their conditions of work produced. The breakdown of this attitude began in the eighteenth century with the pioneer studies of industrial diseases by the Italian doctor, Rammztini. Dr. Clarke stated that economic factors in present-day society distort medical practice and theory. Here, again, the inability to solve the real problems of public health in a society which cannot provide basic nutrition and environment has led the older school into a complete denial of medicine as a science, and to the emergence of irrational and mystical elements.

The symposium, to judge from the unexpectedly large attendance and the animated discussions that followed each contribution, must have supplied a need that has existed for some time. There is room, however, for much more effective coördination of the different contributions, and for developments both in the direction of far more thorough discussion among experts, and clearer popular exposition.

J. D. BERNAL.

NEWS AND VIEWS

Augustin Pyramus de Candolle, For.Mem.R.S.

ON September 9 occurs the centenary of the death of the famous Swiss botanist Augustin Pyramus de Candolle, the contemporary of de Saussure and Prévost and the father of Alphonse de Candolle (1806–93). Born at Geneva, February 4, 1778, he was the son of a magistrate of the republic of Geneva and received a good education. His taste for botany was stimulated by attending the lectures of Prof. J. Vaucher (1763–1841), a founder of the Geneva Natural History Society, and while still in his 'teens de Candolle went to Paris, residing at the house of Dolomieu and becoming acquainted with such as Vauquelin, Fourcroy, Cuvier, Lamarck and Desfontaines. In 1798 owing to the decline, through the political upheaval, of the family fortunes, he took up the study of medicine, but botany still remained his chief study, and in 1804 he began to lecture in the place of Cuvier at the Collège de France. In the summer of 1806 he began a series of official botanical journies through France and Italy, and in 1810 was appointed to the chair of botany at Montpellier with charge of the old botanical gardens.

In 1816 after the Restoration, de Candolle returned to his native land and was made professor of natural history at Geneva, a post from which he retired in 1834 through ill-health, when he was succeeded by his son. A man of the highest character, he was honoured alike by his fellow citizens and by foreign societies. His writings, which began with a memoir on lichens, were very numerous. His great work "Regni Vegetabilis Systema Naturale" was begun in 1818 but the too extensive scale of his work led to the commencement of his "Prodromus Systematis Naturalis Regni Vegetabilis", which was continued after his death by his son and other botanists. It is related that while at Montpellier, after the fall of Napoleon, he was instrumental in saving the Emperor's mother and sister Pauline from the danger of a mob by hiding them in the botanical garden. "Like all truly great men", it has been said, "de Candolle was modest; and the consciousness of his own worth is shown by the lenity with which he judged others, and in the heartiness with which he applauded their services."

Augusto Murri (1841–1932)

PROF. AUGUSTO MURRI, one of the most celebrated Italian physicians of recent times, was born at Fermo on September 8, 1841. He studied medicine at Camerino and Florence, where he qualified in 1864. After receiving post-graduate instruction in Paris, Berlin and Vienna, he returned to Italy, and after a period of private practice became assistant to Baccelli in the medical clinic at Bologna in 1871. Five years later he succeeded Baccelli as professor of medicine, and in spite of many tempting invitations from other Italian universities he remained at Bologna until the retiring age of seventy-five in 1916. His principal publications were devoted to the regulation of temperature, the theory of fever, the Cheyne-Stokes phenomenon, hæmoglobinuria from cold, tumours of the cerebellum, clinical lectures, medico-legal reports, organotherapy and glandular insufficiency. In 1912 he was the recipient of a *Festschrift*. Selections from his works were published by Gnudi and Vedrani in 1919. He died at the advanced age of ninety-one, and on the day of his burial the city of Bologna founded an Augusto Murri prize in medicine.

Contra-rotating Airscrews

MESSRS. ROTOL AIRSCREWS, LTD., have now completed the development, to the production stage, of a constant speed contra-rotating airscrew, the principle of which was mentioned in NATURE of May 17, 1941, p. 602. This model consists of two three-bladed airscrews mounted on the same centre line, normally the engine hub, rotating in opposite directions. The aerodynamic efficiency of this device is not appreciable at flight speeds of less than three hundred miles per hour, but above this it is worth while, and at five hundred miles per hour it gives an increase of about 7 per cent. One particular example weighs 497 lb., compared with 450 lb., for the normal airscrew. Metal or wooden blades of any detachable type can be used equally well. The de Havilland Aircraft Co., Ltd., and the Fairey Aviation Co., Ltd., have also announced the production of contra-rotating airscrews.

The development of this device is the logical answer to the peculiar conditions arising in war machines, in that the increasing powers given by the newer aero-engines are not used to equip larger aircraft, but rather to improve the performance of those of the present-day dimensions. It is not possible to obtain more blade area by increasing the diameter of the single propeller because of ground or water clearance, and also because the blade tip speed, being too high, would make that part increasingly inefficient. Reducing the rotational speed to counteract this would give more slip and make the rest of the blade less efficient, and would call for a considerable gearing down, as the higher-powered engine is usually of high speed itself. Obtaining extra area by increasing the number of blades is not practicable as the thrust of each blade is spoiled by the interference of the preceding blade. There are also other advantages in the flying operation of fighting aircraft which were discussed in the previous note in NATURE.

Architects and Post-War Reconstruction

THE Reconstruction Committee set up by the Royal Institute of British Architects to consider and formulate the policy of the Institute and allied societies in post-war reconstruction and planning in its widest aspects has organized its work in three sections. A small group has been appointed to carry out work involving analysis of the position of the architectural profession in relation to physical reconstruction, and also on practical considerations in connexion with

reconstruction on which the Government may seek advice from the profession. Consideration is being given to the question of professional status, particularly relating to a national planning authority and its regional and local administration, to town planning qualifications, covering an architect's qualifications for town planning and the possibility of including town planning in the curriculum of education of an architect.

A housing group, building legislation group, a building industry group and a building technique group which will consider building science and technique with reference to the probable shortage of certain building materials, and to the possibilities of standardization, prefabrication and the use of synthetic materials are also at work. These groups will record their findings in a concise report for submission to the main committee. A policy group has also been formed consisting of the chairmen of all these groups as well as of the publicity sub-committee which will deal with propaganda on broad lines to demonstrate to the public the immense opportunities underlying national reconstruction and the part the profession can play in this work. The groups are intended to concentrate on co-ordinating existing information rather than initiating new research and the committee has suggested that each group should submit a preliminary report within six weeks and progress reports thereafter at monthly intervals.

Great Britain and the U.S.S.R.

THE Executive and Social Relations Committees of the Association of Scientific Workers have transmitted the following resolution through the Soviet Embassy to men of science and technicians of the U.S.S.R.: "From the Executive and Social Relations Committee of the Association of Scientific Workers to the scientists and technicians of the U.S.S.R.: The Association of Scientific Workers, representing scientists in all branches of science in Great Britain, sends its wishes of goodwill and friendship to the scientific workers of the U.S.S.R. It considers that the closest collaboration in the technical and scientific spheres is essential to the speedy victory of the British and Soviet peoples in their common struggle against Nazi and Fascist aggression. To this end it urges the exchange of technical information and of delegations of scientists between the two countries, and the promotion of personal contact between workers in the same fields."

Monthly Science News (*M S N*)

THE British Council, at the suggestion of its Science Committee, has decided to issue a monthly broadsheet surveying scientific developments in popular terms. The broadsheet is being edited by Mr. J. G. Crowther, secretary of the Science Committee, whose name will be sufficient guarantee that the material presented will be both accurate and readable. The first issue is dated August, and contains paragraphs on the distance of the earth from the sun, a new breed of chicken in which sex is determinable at a day old, barrenness of fruit trees, the two types of diamond disclosed by X-ray examination, the hardening of insect cuticle, and measurement of the temperature of liquid steel. The Press is invited to reproduce any of the material without fee subject to acknowledgment by the initials *M S N*.

The Engineering Industry in the U.S.S.R.

AN informative article by V. A. Bary on "The Engineering Industry in Russia" is published in *Engineering* of August 15. He reminds us that until the eighteenth century, timber was the basic material of all Russian engineering works, and the skill of the carpenters who were the architects and builders of the old Russia was, and remained, of the highest standard of craftsmanship. The first Russian iron and steel industry was established in the central part of the Volga basin and in the Urals. Until the south of Russia developed its own coal and steel industry, the north was the only provider of these commodities and hence the priority of the northern carpenters among the Russian engineering trades. When the first steel tankers to carry paraffin from Baku up the Volga were built in 1880, the wooden-ship builders maintained a vigorous and for some time quite a successful rivalry, using wooden tankers ranging in displacement up to several thousand tons. Similar resistance was offered in bridge-building and other branches of structural engineering to iron and steel.

In 1913, the Russian iron and steel industry produced only about five million tons. In 1938, the output of iron and steel was in excess of 25½ million tons, as compared with the 35 millions produced in Germany. These commodities are the basic materials of engineering, and the comparative figures afford an idea of the growth of the engineering industry over the same period of time. Russia is still primarily an agricultural country, and one of the first directions in which intensive mechanization was pursued was that of providing tractors for farming purposes. There were in 1939 more than six thousand tractor stations distributed over the 540,000 square miles of cultivated land. Air transport of goods, passenger and mails has been extensively developed; 69,000 miles of air routes were in operation at the outbreak of hostilities.

War-time Catering in Canteens

A BOOKLET has just been issued by the Ministry of Food for the benefit of 'British Restaurants', industrial canteens and other large-scale feeding-centres. This booklet has been compiled as a result of a nine-months investigation and experiment in industrial canteens in all parts of England, Scotland, Wales and Ireland, and all recipes have been tested in such canteens. Each day's suggested meal has been built up on the principle of the Oslo breakfast, to provide in one meal a high proportion of the day's requirements of essential vitamins and mineral salts. Averaged over six consecutive days, the analysis is as high as that of the Oslo breakfast.

The aim throughout has been twofold; first to show how it is possible to provide attractive and palatable meals of a high nutritional standard under

the present difficulties of rationing and supplies; secondly, to take the present opportunity of food consciousness to change gradually the food habits of the majority of working-people in Great Britain so that the standard of the national diet is improved rather than allowed to deteriorate. For this purpose, it will be observed that all bread is given as national wheatmeal, a raw vegetable is included in every meal in some form or other, cooked vegetables are suggested in much larger quantities than is usual in canteens and oatmeal or wheatmeal flour is used freely in cooking. The booklet is being issued free to all 'British Restaurants', industrial canteens and Londoners' meal services. Copies can be obtained from the Nutrition Section, Food Advice Division, Ministry of Food, Vincent House, Vincent Square, London, S.W.1.

The Newcomen Society

THE Newcomen Society, which this year attains its majority, has recently issued its syllabus of meetings in Great Britain for the session 1941–42. The presidential address of Col. C. E. Davies will be read on November 12 after the annual general meeting. Thirteen papers are included in the syllabus. Among the subjects to be dealt with are automobiles, Suffolk windmills, spring balances, wood screws, and natural draught furnaces. Dr. Thurston is giving a paper on "The Evolution of Rider Planes for Aircraft", Dr. Herbert Chatley one on the "Development of Mechanism in China", and Dr. Dickinson is giving papers on Robert Stuart Meikleham and Joseph Bramah. Other papers relate to early engineering and iron-founding in Cornwall, the French civil engineers of the eighteenth century, and the famous firm of shipbuilders, Messrs. Normand of Havre. In the *Newcomen Quarterly Bulletin*, probably the last to be issued for the time being, are some interesting quotations from letters received from members in the United States.

Comet Okabayasi-Honda (1940*e*).

IN NATURE of March 29, p. 387, a note about this comet appeared, and it was stated that it was discovered at Tokyo on October 4, 1940. Dr. Issei Yamamoto has pointed out that an error has occurred regarding the place of discovery. Okabayasi is at Kurasiki Observatory, which is under the direction of Yamamoto, and early in the morning of September 30 he discovered the object in Leo, suspecting its cometary character at the time, though he was not able to confirm its motion until October 4. Honda is at the Zodiacal Light Station at Seto, Hirosimaken, also under the supervision of Yamamoto, and independently discovered the comet on October 4. From his long experience as an observer he was immediately convinced that it was a comet and reported his discovery to Yamamoto, who met both observers at Kurasiki on October 5 and cabled to Copenhagen. A telegraphic announcement was also made from Tokyo Observatory, and it is possible that some confusion was caused by this. It is very satisfactory to know that the Astronomical Society of the Pacific has awarded the Donohoe Medal to both discoverers.

Announcements

PROF. LANCELOT HOGBEN, F.R.S., regius professor of natural history in the University of Aberdeen, has been appointed Mason professor of zoology in the University of Birmingham in succession to Prof. H. Munro Fox (see NATURE, June 28, p. 800).

Dr. L. L. Bircumshaw has been appointed lecturer in inorganic chemistry in the University of Birmingham.

THE Minister of Agriculture and Fisheries has appointed the Hon. Mrs. Youard to be an additional member of the Committee set up on July 21, under the chairmanship of Lord Justice Luxmoore, to examine the present system of agricultural education and to make recommendations for improving and developing it after the War (see NATURE, August 9, p. 161).

AT the recent annual meeting of the U.S. National Academy of Sciences, a National Science Fund was established to administer funds for the support of scientific research. The Fund will be managed by a committee under the chairmanship of Dr. William J. Robbins, director of the New York Botanical Gardens, and consisting of seventeen members of the National Academy and twelve others well known in public life or industry.

THE report of University Extension Lectures and Tutorial Classes of the University of Leeds, for the year 1939–40, is a record of steady progress under adverse conditions arising from the War. In all, 78 tutorial classes and 5 sessional courses were attended by 1,063 students. The great majority of the lecture courses dealt with such subjects as literature, social philosophy, economic and political questions and current movements of the day. Of scientific subjects seven courses were held in biology, three in psychology and one each in physiology and geology. The marked absence of any lectures dealing with the physical sciences remains as a challenge to men of science to present their subject in a form acceptable to an ordinary unselected adult audience.

IN accordance with the trust deed governing the Harrison Memorial Fund, the Selection Committee consisting of the presidents of the Chemical Society, the Institute of Chemistry, the Society of Chemical Industry and the Pharmaceutical Society, will make an award of the Harrison Memorial Prize in December. The Prize, of the value of about £150, will be awarded to the chemist of either sex, being a natural born British subject and not at the time more than thirty years of age, who during the previous five years has conducted the most meritorious and promising original investigations in any branch of pure or applied chemistry and published the results of those investigations in a scientific periodical or periodicals. Further information can be obtained from the Secretary, Chemical Society, Burlington House, Piccadilly, London, W.1.

ERRATUM.—In a recent communication (NATURE, 148, 226; Aug. 23, 1941) the dissociation products of carbon dioxide were given as $CO(^3\Omega)+O(^3P)$. This was a printer's error and should read $CO(^3\Pi)+O(^3P)$.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Post-mortem Darkening of Plant Tissues and its Relation to Respiration

THE darkening of plant tissue following extensive mechanical damage is a frequently observed phenomenon and is due to irreversible oxidation of polyphenols. The effect is particularly well marked in the tea-leaf, where the tannin oxidation results in the development of the characteristic copper-red colour of 'fermented' tea-leaf.

It is possible to effect a full fermentation of tea-leaf, that is, a complete oxidation of all the tannins present, while still preserving the cellular nature of the tissue. After fermentation, following extensive mechanical damage, the cell walls are largely intact; and it is observed that the tannins are no longer localized in the vacuoles but are distributed throughout the whole tissue. It follows that rupture of the outer cell wall is not essential for irreversible oxidation of tannins to take place.

The necessary damage to the tea-leaf is best achieved by subjecting the wilted leaf to a shearing force such as is obtained by rubbing it between the finger and thumb or between the palms of the hands. While such treatment has but little effect on the integrity of the outer cell walls, it has been claimed by Phillis and Mason[1] that comparatively small shearing forces have a disruptive effect on the continuous phase of the cytoplasm.

The effect of such shearing forces on the respiratory activity of the leaf is marked. The capability of undergoing anaerobic fermentation may be almost completely inhibited[2] and oxygen uptake under aerobic conditions is also suppressed unless an oxidizable polyphenol is present[3].

Results to be presented shortly interpret this effect in tea-fermentation as due to coenzyme inactivation. The disruptive effect on the cytoplasm may be considered as affecting the orientation of molecules in protein-phosphatide monolayers where adsorption of coenzymes I and II is a necessary adjunct to the transfer of hydrogen from respiratory substrates to carriers of the cytochrome type. The effect of the destruction of the organization of such monolayers will be to inactivate the coenzymes by restricting their sites of activity, and hence to reduce respiratory activity to low levels. If the vacuole originally contained appreciable amounts of polyphenols, these latter substances may now penetrate into the cytoplasm where they undergo direct oxidation by the oxidase system to form deeply coloured pigments. Until this oxidation is complete, the tissue may consume oxygen at a rate higher than that when undamaged, but when the polyphenols are oxidized the uptake sinks to the same low levels found for tissues free from polyphenols. The respiratory quotient during the rapid oxygen uptake is low.

There are other means of inducing irreversible oxidation of polyphenols in vegetable tissues including treatment with anæsthetics such as chloroform, and subjecting the leaf to a temperature of about 50° C. In both these cases it is observed that the cytoplasm is rendered freely permeable to the vacuole contents. Further, the solvent effect of the chloroform on the phosphatides or the denaturing effect of the elevated temperature may be expected to result in a destruction of the organization of protein-phosphatide monolayers fully equal to that brought about by shearing forces.

The effects of anæsthetics, moderate heat and mechanical damage involving shearing forces on the respiratory activity of vegetable tissues are therefore to be considered as essentially similar. Enzyme inactivation is not responsible for the diminution in respiratory activity, and the effects are to be interpreted as due to the inability of the coenzymes to couple the oxidase system and dehydrogenases in the disorganized tissue. Polyphenols present in the vacuole may then penetrate into the cytoplasm to undergo oxidation catalysed by the oxidases. Some secondary oxidation of respiratory substrates by the *o*-quinones may be brought about through the coenzymes now in homogeneous solution, but the respiratory quotient values observed (0·2–0·5) for different plant tissues indicate that the greater part of these *o*-quinones undergo further irreversible changes, with pigment production, before being able to function as hydrogen acceptors in this way.

Blackening of Potato Tubers on Boiling

IT might be of interest to state one or two facts which may have some relation to the hypothesis advanced by Miss Ursula M. Robison[1], that the blackening of potato tubers on boiling is caused by the black oxide of iron produced by oxidation from ferrous iron liberated from a loose complex, probably in association with proteins, as the result of hydrolysis on boiling.

From an examination of potato samples derived from about forty modern replicated fertilizer experiments, designed in association with Dr. E. M. Crowther of Rothamsted Experimental Station, I found that the typical grey to black discoloration which develops after boiling was confined to tubers grown on potash-deficient plots in association with a relatively high nitrogen level in the soil.

It has been shown by various workers that in potash-starved plants the amino acids increase relatively to the protein, and it has been suggested that this is due, at least partly, to the breakdown of protein in the prematurely ageing plants. These changes may cause an abnormal distribution of iron in potash-deficient plants and produce a greater concentration in potato tubers. Hoffer[2] has shown that

maize plants grown under conditions of potash deficiency do accumulate iron compounds in the node tissue and that the tissue develops a dark purplish-brown coloration and breaks down. He actually developed from this observation a method of diagnosing potassium deficiency in the soil, based upon the application of an acid solution of potassium thiocyanate to the nodule tissues of corn stalks when cut open lengthwise.

It would have been interesting to know whether Miss Robison found any significant differences in the potassium content and in the potassium-iron ratios between normal tubers and those that went black after boiling.

Vitamin C Content of Fresh, Canned and Dried Guavas

THE common guava, *Psidium guajava*, has not as yet received the recognition which it deserves as a potent source of ascorbic acid. Both in Hawaii[1] and in India[2], values as high as 300 mgm. per 100 gm. have been reported for the fresh fruit, although many lower values are to be found in the literature.

We have investigated the vitamin C content of guavas from various parts of the Transvaal and the Cape Province. Ascorbic acid has been estimated by titration with indophenol in aqueous or dioxane solution, after extraction of the material with a 2 per cent solution of metaphosphoric acid. Canned guava juice has been assayed biologically by Key and Elphick's modification of the Hojer tooth method, the results being in agreement with those found by the chemical method.

Condition of fruit	Ascorbic acid content in mgm. per 100 gm.
Green and hard	250–350
Ripe and firm	300–450
Over-ripe and soft	50–100

In the above table is summarized the variation of vitamin C content of the fruit as a whole with its condition. It will be seen that the amount of ascorbic acid present in the fruit increases as it ripens but soon diminishes as the guava becomes soft. Firm fruit of high vitamin content may be stored at room temperature for several weeks without serious loss of vitamin but where the guava is ripe or infected with fruit fly the value decreases rapidly.

There does not appear to exist a wide variation in the vitamin content of fruit of different varieties or from various districts. On the whole, however, white-fleshed guavas are usually slightly richer in ascorbic acid than those with pink flesh.

Of the different parts of the fruit, the skin has the highest content, the inner pulp contains little, and the stones none at all. The proportion of ascorbic acid found in skin, outer pulp and inner pulp may be as high as 12 : 5 : 1.

When selected firm fruit is canned the ascorbic acid present in fruit and juice reaches levels of 200–300 mgm. per 100 gm. The use of soft fruit is attended by a sharp decrease in the vitamin content, values as low as 18 mgm. per 100 gm. being found in some cases. These low values also obtain under conditions favourable to the oxidation of the vitamin such as pulping or overcooking.

The most successful procedure for the preservation of the vitamin has been found by us to be drying at low temperature. The unpeeled fruit is quartered, the central pulp and stones removed and the residue blanched for two minutes. Thereafter the fruit is dried at 130° F. for 10–12 hours and powdered. Powdered guava prepared in this manner contains 2,500–3,000 mgm. per 100 gm. (white) and 2,000–2,500 mgm. per 100 gm. (pink). Failure to blanch the fruit prior to drying results in lower values (1,000–1,500 mgm. per 100 gm.). Thus dried guavas compare favourably with other rich sources of the anti-scorbutic vitamin such as dried rose hips, reported by Lund, Spur and Fridericia[3] to contain 2,000 mgm. ascorbic acid per 100 gm. Moreover, the guava powder has a pleasant aromatic odour and practically no taste.

The above results, taken in conjunction with the wide distribution of the various species of guava and the ease with which they can be grown, justify their extensive cultivation and consumption. Full experimental details will be published later.

We wish to express our appreciation of the assistance and co-operation accorded us by officers of the Food Inspectorate (Q Service-Supplies) and the Mobile Laboratory Unit of the South African Medical Corps.

Intergranular Changes in an Iron Alloy

THE phenomenon of intercrystalline attack by liquid metals on solid metallic crystalline aggregates is well known[1], but the recorded cases which we have been able to find are chiefly of the attack of low-melting metals such as tin, solder, lead and cadmium on high-tensile steel, and mercury on copper, nickel and aluminium alloys.

An example has now been met of attack by mercury on high-tensile steel. The steel is of the following analysis and mechanical properties.

Analysis		Mechanical Properties	
C	0·28–0·32 per cent		
Ni	3·75–4·5 ,,	Ult. stress.	c. 105 tons/sq. in.

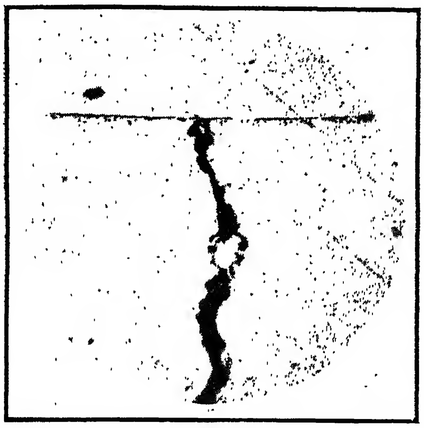
The above mechanical properties are obtained by air-hardening. In a certain application an oil-hardened nickel-chrome steel dowel pin *W* in. diameter is pressed into a hole in this air-hardening steel with a slight interference fit – 0·0001–0·0002 in. A series of failures in service was met. In every instance the fracture had two easily distinguishable zones—an initial zone exhibiting what appeared to be brittle fracture and a secondary zone of well-marked fatigue type spreading from this. Microscopic

sections across the two zones showed no defects in the steel adjacent to the fatigue fracture, but the initial zone invariably showed break-up at the edge of the fracture which was connected with intercrystalline boundaries.



× 250.

Heat treatment, internal stress and mechanical factors were exhaustively explored and the whole workshop process of manufacture overhauled and improved, but no constructive light could be thrown on the problem until it was discovered that one of the operators engaged in making the parts used on occasions a 'mercury ointment' as an aid to fitting the dowels. This ointment is known by pharmacists as Ung. Mercuriale B.P.C. Its use as a lubricant is mentioned in some cheap popular handbooks of engineering, especially for tapping holes in difficult steel, easing tight fits, etc.

Special specimens incorporating a driven-in pin were fitted with the ointment between the surfaces, controls fitted dry being used. Specimens and controls were subjected to reversed bending on a Wöhler type of fatigue-testing machine. Specimen and control were run on the same machine simultaneously. Triplicate tests were made. In two cases intercrystalline attack as shown in the accompanying illustration occurred. In the remaining case early fracture occurred for mechanical reasons connected with the shape of the specimen.

Static tests were carried out by loading a specimen in tensile at 75 tons/sq.in. after amalgamating mercury on its surface. Brittle failure with intercrystalline attack occurred after 36 hours. A specimen without mercury withstood three weeks at 75 tons/sq. in without failure and five days at 90 tons/sq. in. without failure.

The withdrawal of the ointment from the workshops has up to the time of writing and over fourteen months stopped the failures.

It will be seen, therefore, that this seems to be a genuine case of intercrystalline breakdown of high tensile steel caused by the presence of mercury.

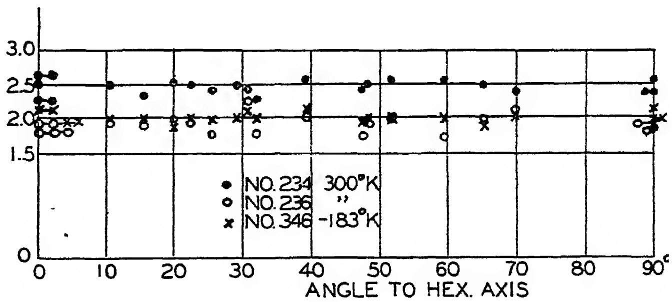
Electron Diffraction Intensities

Under this title, Fordham[1] has discussed the intensity anomalies observed by us in the electron diffraction pattern of zinc oxide. Fordham believes that "variations in extinction due to irregular crystal shape or to anisotropy will explain at least qualitatively many of the observed differences between calculated and observed electron diffraction intensities".

We have considered this possibility ourselves and have discussed it in some detail[2]. Such an effect as we pointed out would have to be dependent on electron energy. However, in the whole range 7–80 kv., no noticeable difference in the intensity distribution of the pattern has been observed, and therefore one must conclude that absorption does not account for the anomalies observed. Several years ago L. Pauling, in discussing this point, raised the question of the influence of the distribution of crystal size in the specimen. He pointed out that it might be possible that the absorption factor could be reduced to a product of a purely geometrical factor, depending on (hkl), and an absorption factor which remains the same for all planes. In this case no dependence on voltage is to be expected for the relative intensities. Calculations by Yearian with a suitable particle size distribution have shown that such a formulation is possible, but that the change in intensity obtained in this way would be too small to reproduce the observed anomaly. It is correct that the form of the zinc oxide crystallites consists partly of very thin filaments. However, the difference in sharpness of the $(00{\cdot}1)$ as compared with the $(hk{\cdot}0)$ diffraction lines is only an apparent one. In the many micro-photometer traces taken in our work, the half-widths for the lines, corrected for background, do not show any appreciable variation as a function of the angle with the Z-axis.



Half-widths in mm. plotted against (hkl), the planes being arranged as a function of angle with the Z-axis

However, the most cogent proof of our hypothesis is found in the fact that it is possible to reproduce the main features of the electron diffraction pattern by determining the F factor with X-rays experimentally, and constructing the corresponding Z–F curve for the electron diffraction pattern[3]. This is also substantiated by the calculations of Johnson and James[4], who show that it is possible to account for this anomaly by assuming a distortion of the valence electron cloud. Some of the minor details of the diffraction pattern may very well be influenced by some second order effect, such as absorption or extinction or temperature-dependency, but the main features are reproduced by the distortion of the electron cloud.

As to the case of evaporated metal films, there is also considerable deviation from the calculated intensity, as we first pointed out some years ago[5]; these anomalies have now been reproduced by Ornstein and collaborators[6]. Therefore a full explanation cannot be made on some such simple assumption as difference in the shape of crystals or different absorption in different direction. Some other effects such as distortion of the electron cloud and dynamic effects of reflexion have to be taken into account.

Social Functions of Science

In recent discussions on the social functions of science not every contributor has escaped the pitfall of confining the role of science to improving material conditions. I venture to offer the following as a restatement of the more fundamental social function, which is presupposed by the purely material function.

The pursuit of natural science may be regarded as a type or microcosm of all rational life. For, first, scientific work employs reason working upon sensible experience; it requires careful seeking of evidence, and constructive interpretation thereof; and consequently demands respect for fact, for logic, for insight and for imagination. Second, it exhibits a rational unity of thought and action, in the continual interplay of experiment and theory. Third, it is a social as well as a personal enterprise; as such, it demands respect for the human person and tolerance for diverse opinions, and favours a mental climate which is a balance of appreciation and criticism. It would not be difficult to work out in greater detail the rôle of natural science as a representative type of rational behaviour. All the above characteristics are to be observed also in the running of a business, a farm, or a family, or in any rationally conducted enterprise. The special methods used, and the results, are different in each case, but the spirit defined by these characteristics is common. Moreover, natural science prepares the mind for other rational disciplines, including metaphysics and ethics, which likewise employ both reason and experience; it shares with them the rational spirit, though dealing with a more restricted aspect of experience.

Now natural science, through its influence on daily life, is becoming for many the most easily recognized form of rational behaviour. Further, so long as it remains alive at all, it cannot fail to exhibit rational standards; false science is easily detected by experiments accessible to all men of science, and moreover, would lead to failures if applied. The most menacing fact of the present time is that the fundamental principles of respect for truth and for the human person (integral elements in the culture bequeathed to us by Christendom) are not everywhere recognized. In the intellectual chaos of our times, natural science may therefore be an important influence in holding many to rational standards. If men will carry the *spirit* learned in pursuing natural science into other and more personal activities (without trying to carry over also the special methods of natural science into fields which are much too subtle and too complex for them), we may hope for a more rational world.

The influence of science in this way is no less important than in providing the technique for changing the material conditions of life—indeed it is infinitely more important, since the wise application of science requires *direction*, which cannot be provided by natural science itself, but only by ethical science and insight. Whether men of science should try to undertake this direction, or whether this social function does not rather stop at propagating the spirit of rational living, is another argument.

Social Education in the Services

Among the three thousand lecturers to the Forces included in the panels of our twenty-three regional committees there are many who offer one aspect or another of science as their subject. The choice of lecturer and topic is, under the agreement made by the Central Advisory Council for Adult Education in H.M. Forces with the Services, dependent upon the expressed wishes of the men and women themselves. It is the function of the Service education officers to ascertain what these interests are. A considerable number of lectures on scientific subjects and classes in either pure or applied science have been provided. The resources of the universities, local education authorities and voluntary bodies have been placed fully at the disposal of the Services for this purpose.

The article in Nature of August 16, p. 173, appears to overlook the existence of all this co-operative activity on the part of the Services and the civilian educational bodies. It might perhaps surprise the writer to learn that on the estimate of the Director of Army Education, a million men and women in the Army attended lectures in the course of a recent month. The demand for educational facilities of all sorts has been maintained right through the summer and may well develop still further during the coming autumn and winter. At a recent conference of regional committee secretaries it was agreed that scientific subjects ought to take a larger place in the programme; but it was pointed out that those who offer them do not always present either attractive titles or an exposition which makes scientific facts and theories relevant to the interests and the thought of ordinary men and women. From this point of view the suggestions made in the article are particularly valuable and I hope that they will be very widely followed by lecturers, actual or potential, to the Forces.

ELECTRICAL DEVELOPMENTS IN MADRAS

IN a paper published in the *Electrician* of August 1, by J. Meek, the resident electrical engineer to the Madras Presidency, interesting projects are suggested about new developments in the Madras Presidency. This Presidency covers an area in South India of 142,000 square miles and supports a population of about 48 millions. An idea of the size may be obtained by comparison with that of England, which has an area of about 50,000 square miles and a population of about 38 millions. The people in the Presidency are mainly engaged in agriculture, and most of them live in villages. The capital, Madras City, has a population now approaching 800,000, but the next biggest town, Madura, has a population of less than 250,000. Four main languages are spoken—Tamil, Telugu, Canarese and Malayalani—and efforts are now being made by the Congress Government to introduce Hindi with the ultimate object of providing India with a common language. Among the educated classes English is widely spoken.

Some idea of the climate of Madras can be obtained from the following significant clause which usually appears in Madras Government electrical specifications: "The temperature in the shade will vary from 50° F. to 110° F. The max. temperature in the sun may be assumed to be 150° F. The relative humidity will vary from 60 to 80 per cent."

Although for the greater part of the year there is very little rain in most parts of the Presidency, there is considerable rainfall during the south-west and north-east monsoons, especially in the eastern and western Ghats, where more than 400 in. is registered in some places.

Until comparatively recently the only supply system of any importance was that of the Madras Electric Supply Corporation, which has held a licence from the Government for the generation and distribution of electricity in Madras City for the last thirty-one years. This Corporation has a steam-turbine power station with a capacity of more than 53,000 kva. The Presidency has no coal or oil deposits but is fairly well provided with water-power in the south. In 1924 the Madras Government decided to take charge of all hydro-electric surveys and projects and bought back concessions previously granted to private concerns which had not been developed.

The Pykara Scheme in the Nilgiri Hills was taken up first. It is situated at a distance of 280 miles to the south-west of Madras. Pykara is a high head scheme with storage utilizing a fall of 3,000 feet. When the great Mettur Dam was built some years ago for irrigation control, hydro-electric pipes were left ready in the dam, and this development was the next to be taken up about five years ago. The present installed capacity of plant is 37,500 kva. operating on a head which varies from 60 to 160 feet. In addition to these schemes the Madras Government has provided two steam stations in the north. There are many miles of feeder lines and also a considerable mileage of 33 kv. and 11 kv. The length of these transmission lines has necessitated the introduction of synchronous condensers at Trichinopoly and Madras.

The demand for power has greatly exceeded the most optimistic estimates, and additional plant and extensions to lines and substations had to be installed several years in advance of the original programme.

The grid supplies power direct to many tea factories, ginning factories, oil mills, chemical works, and even to farmers in outlying districts. More than a thousand small pumping sets are connected to the systems for pumping water from wells into the fields. The ryot has found it cheaper and more convenient to water his fields by means of electricity than by using bullocks as his forefathers have been doing for centuries.

UNIVERSITY OF THE WITWATERSRAND

NEW ENGINEERING BUILDING

ON June 18 at the University of the Witwatersrand, Johannesburg, General the Right Hon. J. C. Smuts, Prime Minister of the Union of South Africa, opened the new Wolf and Hirsch Hillman Building, which forms an important and substantial addition to the accommodation provided for instruction in engineering. Its site, lying to the west of the central block and south of the older engineering block, stands higher than these, and in its lay-out this has been utilized to permit of the formation of terraces and rock-gardens and the provision in an economical manner of a range of garages.

The building consists of two wings running east and west, the larger, about 210 ft. long, being devoted to laboratories and placed on the north side so that it receives the maximum light. The shorter south wing, about 130 ft. in length, provides accommodation for a model analysis laboratory, drawing halls and lecture theatres. The east wing connecting these other two contains the entrance hall and staff offices.

The Department of Civil Engineering provides a four-year course for the degree of B.Sc. (Engineering) which is recognized by the Institution of Civil Engineers as exempting its holders from Sections A and B of its associate membership examination. In the Union, it offers a qualification for those entering the higher technical services of the Irrigation and Public Works Departments, National Road Board, South African Railways and Harbours and other equally important administrations and undertakings.

The new Hillman Building will greatly enhance its facilities by providing spacious and well-equipped laboratories with workshops and stores and ample accommodation for lectures. It has been designed to serve a threefold purpose: (i) to promote the course of training already referred to; (ii) to provide for research into fundamental problems of civil engineering; and (iii) to assist in the solution of problems arising in practice.

The main features of the Hydraulics Laboratory are a level flume, 3 ft. wide, 2 ft. 6 in. deep, with an overall length of 82 ft. and glass sides to allow of easy observation; a smaller flume with one end capable of being given a maximum tilt of 1 in 20; a river model table 10 ft. wide and 70 ft. long for the study of river and tidal flow; and a general purpose bench for experiments on the flow of water in pipes.

In the Structures Laboratory, a 350,000-lb. precision hydraulic testing machine has been installed for compression and bending tests. This is fitted with an automatic loading device giving ten different rates of loading and reading to the nearest 10 lb. A 75,000-lb. machine for tensile tests and permitting of compression and bending tests on short struts and beams is on order and will have autographic load-deformation recording apparatus. There are also several test-beds for testing members and structures, and the accessories provided are of the latest types.

The investigation of structural problems by various methods of mechanical analysis employing small-scale models will be carried out in the Model Analysis Laboratory, the equipment of which includes a Continostat apparatus for the experimental determination of influence lines using spline models and a Lobban deformeter. In the Highway Engineering and Materials of Construction Laboratory the main space has been divided into three sections: (1) tar, bitumen and asphalt; (ii) soils and aggregates; (iii) cement and concrete. Each has been suitably provided with apparatus and equipment which will enable tests and investigations to be carried out in conformity with present-day practice in this field, in which there is so much scope for development.

IRISH SALMON, SEA TROUT AND EELS

THE Fisheries Branch of the Irish Department of Agriculture has published a brief summary of the catch of salmon, sea trout and eels in Eire between 1927 and 1939*. Alternate years only are given, the figures are neither averaged nor compared, and no comments are made or inferences drawn. But the statistics themselves are of no small interest, as the following epitome of part of them is enough to show.

	1927	1929	1931	1933	1935	1937	1939
Salmon							
Total catch (wt.)	100	48	75	68	78	45	46
do. rod only	100	24	53	31	50	38	34
Average wt. per fish (lb.)	12·9	13·5	9·7	11·8	9·8	10·7	10·2
	100	105	75	91	76	83	79
Value per rod (shillings)	189	77	85	66	84	69	72
	100	41	45	40	49	37	38
Sea Trout							
Total catch (wt.)	100	101	101	91	100	96	101

The period is not long enough, nor the data complete enough, to let us speak of any lasting *trend*; but it is clear that the catch of salmon has greatly diminished of recent years. Since 1927, the annual catch (as shown in alternate years) has never reached 80 per cent, and has three times out of six been less than 50 per cent, of that year's catch. The catch by rod is worse still; for it has been so low as a quarter, and has only once been more than a half, of the catch of 1927. On the other hand, the catch of sea trout, while it has its ups and downs in the various rivers, averages out over all to a nearly constant total, year by year.

More remarkable than the diminished catch of salmon is a diminution in the average weight of the same fish. From 1931 onwards the average weight has been much below that of 1927–29; and in the last five annual periods it has only averaged about four-fifths of the weight in the first two.

The returns from the several rivers or fishery districts show many interesting things. We have seen that the salmon catch of 1939 was only 46 per cent of that of 1927; but the decrease, though it extended well-nigh all round the coast of Eire, was very far from uniform. The three contiguous east coast districts, Dundalk, Drogheda and Dublin, had in 1939, 90, 99 and 90 per cent of the catch of 1927; but the next succeeding regions, on the south-west and south coasts, namely, Wexford, Waterford, Lismore, Cork and Bandon, show only 34, 38, 26, 21 and 19 per cent, in the same comparison. The commercial importance of all these statistics is, as usual, the least interesting part of them. D. W. T.

* Eire: Roinn Talmhaidheachta (Department of Agriculture), Brainse Iascaigh (Fisheries Branch). Statistics of Salmon, Sea Trout and Eels captured during each of the Years 1939, 1937, 1935, 1933, 1931, 1929, 1927. (P. No. 4658.) Pp. 20. (Dublin: Stationery Office, 1941.) 6*d*.

ELECTRIC STRENGTH OF SOLID DIELECTRICS

IN a paper, by W. G. Standring, of the National Physical Laboratory, which is published in the Power Engineering Section of the *Journal of the Institution of Electrical Engineers*, of August, a discussion is given of the behaviour of a number of insulating materials under disruptive voltages. Experiments were carried out with the object of filling large gaps in our knowledge in a field which has only been partially explored. At the present time, a knowledge of electric strength is of twofold interest. It is of fundamental importance to the engineer, and values of electric strength should provide guidance to the mathematical physicist in developing theories to explain the mechanism of electric breakdown.

Measurements of the electric strength of solid dielectrics have been made on samples up to a few millimetres in thickness. The values obtained are of the same order as those maintained on thin samples under maintained voltages. They indicate that a solid dielectric has a characteristic strength or gradient which causes breakdown, independent of thickness and not greatly dependent on the rate of application, or on the duration of the stress. Continental physicists have formed a similar conclusion for liquids.

Secondary phenomena such as surface discharges and thermal effects are more easily eliminated under impulse conditions than under sustained voltages, since short time limits the production of effects such as the generation of heat, and because a wider range of liquids exists for the selection of a satisfactory immersion medium. In measuring the electric strength or gradient which causes breakdown of solid dielectrics, an immersion medium is necessary to avoid flash-over; also breakdown must not occur first in the medium of the electric field applied to the material under test, as the field is then disturbed and deduction of the breakdown stress from the applied voltage and the geometric configuration becomes impossible. It is not usually practicable to embed electrodes in a solid dielectric in such a way that only the material under test is stressed.

In general, gases have lower electric strengths than liquids and liquids than solids. Discharges may therefore occur in the surrounding medium before the breakdown gradient of the material under test is reached. These discharges act as pointed extensions of the electrode with high concentration of stress at their tips, and the solid test material may break down owing to the local incalculable stress or on account of the high local temperature of the discharge. It is therefore necessary to avoid discharges in the immersion medium. Glycerine has been found to be a suitable immersion medium for testing many dielectrics at atmospheric temperatures under impulse voltages.

Mr. Standring points out that in forming physical theories of the mechanism of breakdown, experimental data on crystalline materials such as mica are likely to be of most help. When maximum results were used, the highest value obtained on the thinnest light amber was nearly the highest obtained with the best mica, which was the same at all thicknesses. For purposes of physical theory, therefore, it may be desirable to take the highest experimental values obtained rather than the average value.

ACCRETION THEORY OF STELLAR EVOLUTION

BEFORE the advent of the accretion theory of stellar evolution, physical theory had progressed sufficiently to suggest the transmutation of hydrogen as providing practically all the stellar energy. Astronomical evidence, especially from double stars, led to the view that there must be a further potential source of energy from outside the stars which replenished the hydrogen in the stars. The existence of interstellar matter in gaseous form in certain regions of the galaxy was known but this knowledge did not simplify the problem. The chief constituent of the cloud was regarded as calcium, and possibly other similar elements such as sodium were also present, but accretions from such elements would merely increase the mass of the star and would not prolong its life.

The subject is dealt with in a recent paper by Messrs. F. Hoyle and R. A. Lyttleton (*Mon. Not. Roy. Astro. Soc.*, **101**, 4, 227), though most of the authors' work has been published elsewhere[1] on different occasions. In their discussion of the problem they postulate the presence of a hydrogen cloud and then consider the conditions which such a cloud must satisfy. The formula arrived at for the rate of change of mass when the motion has become steady is

$$\frac{\partial M_A}{\partial t} = 18\gamma^2 M^2 \rho / \bar{v}^3,$$

where ρ is the density of the cloud in the neighbourhood of the star, M the mass of the star, γ the constant of gravitation and $\bar{v}$ the relative velocity of the star and cloud appropriately averaged to allow for the motion of the star in the galaxy.

Three hypotheses are stated as the requirements of the accretion theory formulated by the authors:

(*a*) That the cosmical cloud in its regions of highest density contains an appreciable proportion of hydrogen molecules—10 per cent by mass would suffice;

(*b*) That the cosmical cloud is not everywhere evenly distributed but possesses local small irregularities;

(*c*) That the cosmical cloud is irregularly distributed also on a large scale, and in particular it is strongly concentrated towards the galactic plane, where the density rises to the value of order 10^{-21} gm. per c.c.

In the solution of the problem of the source of energy of the bright stars the authors invoked a hypothesis which, they claim, has also solved the question of the dynamical evolution of binary stars, and hence the new process has unified the dynamical and physical evolution of stars. In the accretion process no question of a mechanism unknown to science is introduced and thus speculation is almost entirely absent in the theory—a remark that cannot be applied to other theories, for example, that of the complete annihilation of matter. Nevertheless if, as is possible, future investigation should disprove one or more of the three hypotheses previously referred to, the theory would require considerable modification or it might be necessary to abandon it.

Evidence is cited to show that there is support for the hypotheses. Thus, (*a*) requires an appreciable proportion of the cloud to be in molecular form, and Adams and McKellar have recently found the occurrence of vibrational-rotational transitions in the molecules CH and CH in the cosmical cloud. The hypothesis (*c*) may be doubted by many, but one very interesting result follows from the asumption, which is confirmed; namely, that the most massive and luminous stars should be concentrated to the galactic plane. As this agrees with observation a result is obtained for which theoretical astronomy has not previously been able to give any adequate explanation.

Many objections have been urged by Atkinson[2] and these are dealt with in the paper, but limits of space forbid a detailed consideration of these. One, however, is worth noticing. Atkinson considers that a density 10^{-21} gm. per c.c. near the galactic plane is too high. It is interesting to notice, however, that Jeans has obtained central densities of the order 10^{-21} for a number of extra-galactic nebulæ of the spiral type, and the objections could not apply to stars situated in

these external galaxies. Objections relating to the high rate of increase of mass given by the formula, the difficulties regarding the time-scale, the lack of any observable distinction separating stars of small velocity from those of slightly higher velocity, etc., are considered by the authors who, if they have not established their theory, have indicated certain lines along which investigations should be conducted. Reliable observations which supply information of the density distribution and velocities of the stars relative to the cloud will confirm, modify or disprove the theory.

FISH OILS

PRIOR to the War, the fish oil industry was successfully applying to problems of production the results of recent research, particularly with respect to vitamins A and D. The liver oils from some species possess extraordinary potency, thus the blue-fin tuna or horse mackerel yields oil containing up to 400,000 I.U./gm. of vitamin A and 60,000 I.U./gm. of vitamin D as compared with 800 I.U./gm. (A) and 100 I.U./gm. (D) for average cod liver oil. The soupfin shark liver contains 40–70 per cent of oil the vitamin A potency of which is frequently more than 100,000 I.U./gm., but on the other hand it is very poor in vitamin D, the potency being only about 20 I.U./gm. This oil is produced on a large scale in California at relatively small cost, and is probably the cheapest source of vitamin A in a highly competitive market.

The discovery in 1937[1] that oils extremely rich in vitamin A can be obtained by extracting the intestines of fish like halibut, has been followed up commercially on the Pacific Coast, but the nature of the raw material demanded modifications in technique. These have been kept secret. According to Brocklesby[2] 126,000 dollars worth of halibut livers and 37,000 dollars worth of intestines were landed at Prince Rupert, B.C., in 1938. In 1939, 3,853 cwt. of halibut livers yielding 650 gal. oil compared with 688 gal. visceral oil were produced in British Columbia. Fishing for halibut in the Pacific is regulated by an international agreement between Canada and the United States, and the annual quota is about 46 million lb. of which about a quarter is landed in Canada. The viscera account for about 2 per cent of the weight of the fish and the oil content (1–5 per cent) is low. The vitamin A potency is, however, usually two or three times greater than that obtained from the liver. The characteristics of commercial halibut visceral oil are given in detail by Brocklesby and his colleagues.

The viscera from various species of salmon yield a few per cent of oil containing usually more than 5,000 I.U./gm. and 100 I.U./gm. of vitamins A and D respectively. Very large quantities of oil are extracted from salmon cannery waste and the commercial salmon oil is of considerable value for poultry feeding, as well as having other important uses.

PLANKTON STUDIES

IN two important papers, Gordon A. Riley continues his investigations on the interaction of the plankton with its environment ("Plankton Studies. 3. Long Island Sound", *Bull. Bingham Oceanograph. Coll.*, Peabody Museum of Natural History, Yale University, 3, Jan., 1941. "Plankton Studies. 4. Georges Bank", *ibid.*, June, 1941). The preceding work ("Plankton Studies" 1 and 2, in the same periodical, 1938 and 1939) dealt with the Tortugas region and the western North Atlantic. Light and dark bottles filled with natural sea water and suspended near the surface were used to determine oxygen production and consumption, the utilization and regeneration of nutrients and the production and consumption of chlorophyll. Analyses were made of oxygen, chlorophyll and phosphates in the Long Island surface waters for a period of about a year. Counts were made of zooplankton and, during the last half of the investigation, nitrate determinations were made.

The quantity of chlorophyll in the phytoplankton was much higher than in the oceanic waters outside the sound. The nutrients, particularly phosphate, were also high; the ratio of nitrate to phosphate low. The amount of photosynthesis was influenced directly by the quantity of chlorophyll and by temperature and light. The similarities between experimental results and the events in the free water were considered sufficiently marked to permit the use of the former in making rough estimates of productivity.

In the latest paper an analysis was made of the methods of measuring phytoplankton, and it was found that the determination of plant pigments (after the method of Harvey, 1934) has the highest mean correlation with other types of measurement and is therefore the most nearly representative determination of phytoplankton. This portion of the work is a study of the quantitative aspects of the phytoplankton of Georges Bank in relation to the environmental factors which influence its growth and distribution. It is part of a general survey of Georges Bank by several investigators, the purpose of which is to obtain needed information about the spawning and larval development of the haddock.

NATURE

SATURDAY SEPT. 13, 1941

PLANNING REBUILDING AND DEVELOPMENT

THE interim report of the Uthwatt Committee on Compensation and Betterment has rightly been hailed as marking a definite stage in dealing with those problems of physical reconstruction in Great Britain which are now generally recognized as urgent. There is little dissent from Lord Reith's own view that they are urgent and pressing and that without diverting energies from the prosecution of the war, preparations must be made now to plan the rebuilding of Britain, and to consider the reconstruction of devastated areas, the location of industry, the preservation of the countryside and the conservation of natural resources. Only by planning now can we be ready to use the opportunities of rebuilding on better lines when the War comes to an end, and avoid mistakes made after 1918 which are now everywhere admitted.

The urgency of planning arises from two sources. The ground has to be prepared both with knowledge, without which future planning will not be equipped to serve any useful purpose, and with the machinery without which it will not operate at all. The first consideration involves research, the second legislation; and unless both are ready when the time comes, the opportunity will be missed, because the wrong forces may take control and plans are made hurriedly to meet partial difficulties without reference to wider or ultimate purposes. The real obstacles to planning have not been removed by bombing, and the main and urgent task is to see that they do not operate as before through lack of technical data, confusion of social and economic values, or the absence of legislative and administrative machinery.

Research for this purpose involves both technical and social study. As an admirable article in the June issue of the *Architectural Review* points out, architects do not know nearly enough about the new materials of their art, the new resources of modern science, or the needs their work has to meet. Minimum standards require translation into ideal standards based on profound scientific and social research. The sequence from this point of view is first the investigation of actual needs, then of available ways of meeting those needs and finally legislation to enable the resulting plans to be put into effect with efficient organization of the work.

On one point there is widespread agreement—the absolute necessity for an overriding authority. From the report of the Barlow Commission to that of the Uthwatt Committee itself, all the numerous bodies attacking the problems of reconstruction have assumed the establishment of a central planning authority, which would proceed to work out a national plan. The same point was strongly made by Lord Zetland at the recent annual meeting of the National Trust. The only

differences of opinion lie in the exact nature of the authority and the extent of its powers.

Much has already been done to prepare the ground. Following on the attention directed to problems of planning by the P E P report on the location of industry, and by the subsequent report of the Barlow Commission, many excellent articles and pamphlets have served to educate public opinion in the steps required. Among the more recent of such may be mentioned a further article on problems of reconstruction in the *Round Table* of June, the "Rebuilding Britain Series", the first of which. "Overture to Planning", by F. J. Osborn, has just been published*, and the admirable survey number (July) of the *Architectural Review*, devoted to the subject. Valuable features of the latter survey are the introductory account of the work of the Ministry of Reconstruction under Lord Addison during and after the War of 1914–18, and the account of the activities of a number of the bodies already at work in the field.

A number of these have already reported. The Architectural Science Group of the Royal Institute of British Architects has issued a report on the steps to be taken to foster a scientific approach on the part of the architect to his professional duties. The Council of the Garden Cities and Town Planning Association has submitted to the Cabinet a memorandum on "Town Planning in Relation to the Present Emergency and After-War Reconstruction". The Town Planning Institute has furnished two memoranda to the Uthwatt Committee, and has also prepared a report on compensation and betterment indicating the necessary developments of the general law of town and country planning. Memoranda already circulated by the Social Reconstruction Survey set up by Nuffield College include a "Note on the Shift of Population in the Great War", by M. P. Fogarty, a "Survey of Industrial Development in Great Britain Planned since the Commencement of the War", by P. W. S. Andrews, and a further memorandum by M. P. Fogarty on "Demobilisation and Transfer of Industry to a Peace Basis". Various relevant reports have also been issued by the Association of Architects, Surveyors and Technical Assistants.

A good example of the work which is being done in examining the problems of reconstruction in good time is provided by a report which has been published by the Oxford Preservation Trust giving the recommendations of its Committee on Planning and Reconstruction on some general aspects of the post-war problem. The future of the university city is still under consideration and will be the subject of an elaborate study already in preparation. In the present report the Committee, carrying on an inquiry initiated in peace-time, covers ground of interest to many areas all over the country, and discusses the problems involved in the future of Oxford as a great shopping, entertainment and distributing town and the administrative centre of public services over two counties and beyond.

The report indicates concisely some of the points upon which agreed conclusions by the planning authorities in Oxford and the surrounding district are essential; for example, the desirable ultimate population of a district within a radius of six miles of Carfax, having regard to essential public services, traffic relief or congestion in the central area, the conservation of urban amenities, agricultural land and a green girdle, and the provision of subsidiary community centres. Decisions as to the amount of industry desirable in the district, the maintenance of the balance of industry, the exclusion from the city of industries for which it was not planned and for which it is physically unsuitable, and the segregation of any industries in properly designed factory areas or small industrial estates are also imperative. The Committee also recognizes that, if a planning authority is to have freedom and initiative, the difficulties created by the multiplicity of private land ownerships and questions of compensation must be removed.

The Committee recommends the establishment of a regional planning board for an area comprising the City of Oxford, the County of Oxford, less the borough and rural district of Henley, and the part of Berkshire that lies north of the Berkshire Downs watershed. The board would plan the whole area, working to a single general plan and giving full consideration to the interests of agriculture and rural community life in general. The report stresses the importance of preventing ribbon building and makes concrete suggestions to remedy this situation as well as that arising out of private ownership of land and questions of compensation. It suggests a national planning fund to promote the creation of national parks as well as for the preservation of the coast line and its amenities; and it strongly emphasizes the need for a single Government department dealing with town and county planning, emphatically endorsing the unanimous conclusions of the Royal Commission on the Distribution of the Industrial Population regarding a central planning authority.

The establishment of such a central planning authority and the enactment of legislation dealing with compensation and land values are the points

* Overture to Planning. By F. J. Osborn. (Rebuilding Britain Series, No. 1.) Pp. 29. (London: Faber and Faber, Ltd., 1941.) 1s. net.

upon which opinion is clearly agreed as urgent. They are the keynote in the recommendations of the Uthwatt Committee itself, which assumes the establishment without delay of a central planning Authority which will proceed to work out a national plan. The Expert Committee then recommends that the Government should now announce, as a general principle, that compensation ultimately payable in respect of public acquisition of land or of the public control of land will not exceed sums based on the standard of "pre-war values", that is, values at March 31, 1939. This maximum should be adopted for the whole period required to determine the long-term policy of planning and to work out any alterations in the present principles governing compensation.

The Committee then recommends that the legislation to be introduced to establish the central planning authority should vest in that authority the power of controlling building and all other developments throughout Great Britain by reference to national planning considerations and with the view of preventing work being undertaken which might be prejudicial to reconstruction. Such power should come into operation forthwith and continue while the broad lines of reconstruction are being worked out. Areas which may possibly form the subject of a reconstruction scheme should be defined by the competent authority, and the areas prescribed, without waiting for the end of hostilities, so soon as a reasonable judgment can be formed upon the matter by the competent authority. The Committee further recommends that from the date when the controls recommended cease to be operative over all developed areas, no works of reconstruction or development within the specified "reconstruction areas" should be permitted, except with the licence of the central planning authority, for a further reasonable period after the end of hostilities while detailed schemes of reconstruction are being worked out and the areas to which they apply are finally determined.

The essence of the Uthwatt report is accordingly the note of urgency and the establishment of a central planning authority. The principle of the latter has already been accepted by the Government, as was announced by Lord Reith on February 26 and again in the House of Lords on July 27, when he said the Government had accepted the recommendation of the Uthwatt Committee that the cost of land required for rebuilding under a public planning scheme shall not exceed its pre-war value and also the principle that reconstruction areas should be planned as a whole and defined as early as possible. Financial gain by individuals out of landed property by reason of war conditions or post-war reconstruction is to be excluded, as well as a piecemeal patching up of damaged areas.

A central planning authority is required as an urgent emergency measure in order to secure the main purpose and to control rebuilding from that point of view as well as in regard to conservation of labour and materials. This step the Government has postponed in favour of a council of three Ministers consisting of the Secretary of State for Scotland, the Minister of Health, and the Minister of Works and Buildings as chairman. This Council is intended to function until a central planning authority is set up in its final form. This proposal has indeed been welcomed by Sir Montague Barlow as a definite step forward, on the grounds that a long-term planning policy will develop progressively, and that the Council is charged with the duty of ensuring that the administration of town-planning legislation and of legislation implementing the Uthwatt Committee's proposals shall march in step with such long-term planning policy. As the debate in the House of Lords showed, such confidence does not appear to be general. The apparent shelving of the primary recommendation of the Uthwatt Committee has led to widespread disappointment and criticism. It suggests that a forward planning policy is still very much in the clouds, and doubts may very legitimately be entertained as to whether the proposed Council of Ministers already heavily burdened with departmental duties will be able to rise above the level of an interdepartmental committee, the members of which primarily hold a watching brief on behalf of the rights and powers of their own departments.

In the event, of course, such fears may prove to be groundless. Lord Reith's own statement showed that the Government is alive to the importance of having planning systems and plans ready at the end of the War, and of the obvious consequences of being unprepared for peace. Those who are most anxious to see Lord Reith at the head of a central planning ministry with an adequate staff will only be too glad if the present step does avert definite evils before the War is ended and implement the surveying of the ground so that active reconstruction can proceed when the moment arrives. They should find some further reassurance in the attention to research which is already being given by Lord Reith. There has been nothing in his statements to warrant the belief that he will lose great opportunities by small thinking.

There are indeed other fields to which attention must be given. As the *Round Table* points out, there is general agreement that the structure of our system of local government is in many respects out of date. The old boundaries do not fit modern

conditions, and the areas are often too small for present-day services. The creation of a network of regional planning authorities is generally recognized as essential, and this step might in turn assist in dealing with the difficult boundary question as well as in the devolution of authority between central Government and local authorities. There is the further thorny question of the granting to planning authorities of very large powers of land purchase, sufficient to carry out the most comprehensive schemes. Again, positive rather than negative policy is required to eliminate ribbon development, while as the Oxford Preservation Trust emphasizes, agriculture, too, must be represented on the planning authorities and such interests fully safeguarded.

What matters most may well be the kind of stand made in the next few months by those who can speak with authority and experience on the subject of planning. Whatever their preoccupation with war-time tasks, those who have thought for years about the wider issues of town and country must guide the tremendous public interest which the Uthwatt report and Lord Reith's statement have further stimulated. Unless the fundamental issues are made plain and kept unconfused before the public, the old mistakes will be repeated and the future planning of Britain, which is already being shaped, will crystallize in forms defeating once more the high hopes now entertained.

That task of sane, clear thinking and patient, fearless, unprejudiced exposition is one which demands the co-operation of all men and women of good will who look for the building of a nobler and better Britain. They must supply the driving force to ensure that the strategy of planning which can start from the decisions already taken by the Government is made ready for immediate application. Their interest and support can well inspire the Uthwatt Committee as it proceeds with its investigations, and stimulate the rapid framing and placing before Parliament of the legislation already required. They can assist to bring local authorities together in conferences and encourage them to prepare for the duties and developments which the future holds for them.

Scientific workers have their own special part to play. For some there may be participation in the technical side of planning, in the scientific and sound research which must form its basis. For others there may well be response to the appeal in the *Round Table* for a larger number of men and women of character, energy and ability to accept the burdens of the indispensable form of public service represented by the local authorities; and there can be few who could not make some use of such an exposition of the subject as is given in the *Architectural Review*, with its analysis of the main questions and issues, to take part in the task of educating themselves and their fellow-citizens as to the decisions to be taken, the problems to be solved and the efforts demanded of all if Britain is to be replanned and rebuilt on lines worthy of the sacrifices now being made.

SCIENCE IN THE SIXTEENTH CENTURY

A History of Magic and Experimental Science
Vols. 5 and 6: The Sixteenth Century. By Prof. Lynn Thorndike. (History of Science Society Publications, New Series 4.) Vol. 5. Pp. xxii+695. Vol. 6. Pp. xviii+766. (New York: Columbia University Press; London: Oxford University Press, 1941.) 66*s*. 6*d*. net.

THE sixteenth century is commonly regarded as marking the birth of modern science. It owes this distinction mainly to the achievements of a small number of men, of whom Copernicus, Vesalius, Gilbert, Tycho Brahe, Gesner, Libavius, Bruno, Fracastoro and Porta are the most famous. These constituted a very small percentage of the authors who enjoyed some sort of reputation among their contemporaries for their views on natural phenomena. Prof. Thorndike deals with about 1,200 such writers. The vast majority of them were of little, if any, scientific importance.

As a whole, the sixteenth century was more medieval than modern, and showed great credulity rather than an appreciation of the spirit and method of science. Of originality it showed extremely little. Most of its more sensible ideas, and nearly all its superstitions, were derived from earlier times. Although there was some diversity in the sort of superstitions which the various authors adopted from their predecessors, the diversity was neither great nor important. The practice of magic rites declined, but the belief in magic, astrology and all kinds of 'mancies' (aeromancy, geomancy, hydromancy, necromancy, etc.) continued to go strong. Even sceptics or atheists like Sanchez and Vanini could not escape the coils of superstition; and the few pioneers to whom the age owed its place in the history of scientific progress shared to an amazing extent in the credulity of their contemporaries,

though fortunately they managed to keep their best work sufficiently free from unscientific encumbrances. The intellectual atmosphere of the environment influences even great men. It would ill become us to be severe on them, considering the alarming extent to which astrology, alchemy, etc., still continue to engage the interests of the twentieth century, the intellectual and moral instability of which recent events have exposed only too glaringly.

Some readers may wonder whether it was worth while devoting two big volumes to a horde of writers, most of whom were little more than parrots, or plagiarists, or charlatans. But a scholar has a right to determine his own field of research. Prof. Thorndike is obviously interested in the sixteenth century as such, and he has succeeded in portraying its mentality with the aid of the large sample he has surveyed. The picture is not exhilarating, but it is true to life. The average historian of science is not concerned with any period as such, only with the *progress* of science in it, so he ignores the authors who have not contributed to that progress. This likewise is a justifiable attitude. There is no reason for quarrelling over this difference in attitude, as Prof. Thorndike occasionally seems inclined to do. The sensible historian will not retort by deprecating Prof. Thorndike's 'antiquarianism', but will know what use to make of it. The very possibility of writing history, as, indeed, of most studies, depends on selection; and selection always involves the risk of important omissions. By examining, and reporting on, such masses of frequently neglected material, scholars like Prof. Thorndike render a real service to the historian of science. At best, the result may be additional information, or correction; at worst, the historian will at least have the feeling that he may ignore so much with a good conscience.

Prof. Thorndike's volumes have "experimental science" as part of their title. The expression usually means "the systematic study of natural phenomena under conditions controlled by the investigator". The author, however, must be using it in the older sense of "any kind of alleged knowledge professing to be based on experience". For the amount of experimentation dealt with in these volumes is quite negligible. The experiments reported are extremely few and simple, and even the merely observational verifications referred to are mostly of a poor scientific standard. The best experiment cited is that by which Carpi showed, by injecting water with a syringe, that there is no sieve in the kidneys. The most amusing one is that by which Henry VII refuted a certain astrologer who had predicted the king's death before Christmas. He summoned the astrologer and asked him where, according to his astrological knowledge, he expected to spend Christmas. The astrologer replied that he would be at home. Thereupon the king had him imprisoned in the Tower of London until after Christmas. It is regrettable to find that Queen Elizabeth did not profit from this royal refutation of astrology, but was rather addicted to it, and taken in by charlatans.

Prof. Thorndike does not give a full account of the scientific work of the major pioneers, nor does he add much to our information about them. But he does sometimes throw a little new sidelight on them, or suggests new ways of regarding them. As an example of this, some of his comments in connexion with Copernicus may be indicated briefly. Ideas of a moving earth were spreading already, before and independently of Copernicus, so that even some of his ecclesiastical contemporaries were prepared for the appearance of his "De revolutionibus", and so far from opposing its publication, actually tried to hasten it. Partly, it is true, this interest was prompted by the hope of a new astrology to be based on the new astronomy; but that is a detail. The main obstacle to the early spread of Copernicanism was not religious opposition, but the lack of a suitable text-book for beginners. The writers of the many introductory books on the rudiments of astronomy found it much easier to follow the conventional methods of presenting Ptolemaic astronomy than to follow the intricate novelties of Copernicus. The result was that few really understood the new astronomy; and people generally tend to condemn what they fail to understand. If Galileo had used his great gifts to write a graphic elementary account of Copernican astronomy, instead of writing his provocative "Dialogue concerning the Two Chief Systems of the World, the Ptolemaic and the Copernican", things might have been very different.

Prof. Thorndike's work contains also a considerable amount of bibliographical and kindred information. It is noteworthy that of the authors discussed the British are fewer than the Spanish. Of the three hundred printers and publishers referred to only nine were in London, whereas Venice could boast about fifty, and Paris about thirty-five. Apparently through some oversight, the list of printers in Appendix 6 does not include the famous Elzevir.

No one can fail to appreciate the labour, patience and learning that have gone to the writing of these volumes, which, together with four earlier ones, complete a remarkable survey of sixteen centuries of thought about natural phenomena. Prof. Thorndike richly deserves the warm congratulations and gratitude of all who are interested in the history of human thought.

A. Wolf.

GROWTH OF SCIENCE IN CANADA

History of Science in Canada
By Frank Dawson Adams, W. Lash Miller, Frère Marie-Victorin, J. R. Dymond, Leo E. Pariseau, J. J. Heagerty, W. E. Harper, Samuel Beatty, A. Norman Shaw. Edited by H. M. Tory. Pp. vi+152. (Toronto: The Ryerson Press, 1939.) 2.50 dollars.

It is likely that in most of the new countries of the world science takes dominant place alike in the educational field and in popular esteem. Circumstances combine to promote the development of scientific knowledge of one kind or another. Not only does the development of new resources give a direct economic stimulus to science but also there is probably a deeper influence at work and that is the stirring phenomenon of growth of a young country. New cities springing up, oil discovered here, minerals there, new industries born, railroads built, forests cut—these things make their mark upon the minds of the people so that they have an urge towards fresh knowledge. It is not the study of the old, not classics, nor even literature or history, but science which has the widest popular appeal and to which young students turn in ever-increasing numbers. Factors such as these lie behind the long story of the remarkable development of science in Canada which is told here.

The book consists of nine papers presented to the American Association for the Advancement of Science in 1938 to direct the attention of the Association to the growth of science in the Dominion. These papers, written by leading Canadian men of science, are edited and introduced by H. M. Tory, past-president of the Canadian National Research Council. He stresses the rapidity with which science progressed in the past sixty years in both Government departments and teaching and research institutions. The foundations of Canadian science were of necessity laid by men from overseas (whether as pioneers or trained scientists) but in course of time Canadian-trained scientists took their part in both research and teaching, until to-day Canada supplies a fair quota of scientific work and leadership.

Chapter i, by F. D. Adams, is devoted to the history of geology in Canada, from the 1820's onwards. The first work was done by officers of the British army and navy stationed in Canada. Amongst these was John Bigsby (the founder of the Bigsby Medal) who prepared one of the very earliest geological maps of North America. The next stage was the appointment of W. S. Logan as Government geologist in 1842. There was then no staff, equipment, laboratory or library. Undaunted, Logan acquired a few assistants and started the Geological Survey of Canada on its course. Among the earliest work undertaken were studies of the pre-Cambrian rocks of the Canadian Shield, work which was—and is—among the foremost contributions to geological knowledge. Economic developments within the Dominion are reflected in the economic aspects of the publications of the Geological Survey. The winning of ores, the opening of coal- and oil-fields, all are events in which it has played a leading part. The work of geologists in the universities is also outlined. Naturally, the demand for trained geologists has greatly stimulated the teaching of this subject.

Lash Miller writes amusingly about the early days of chemistry in the universities and also touches upon some of the major developments in chemical industry. A brief chapter on Canada's contribution to the science of botany, by Frère Marie-Victorin, is somewhat disappointing. The botanists may well feel that their work has not been adequately described and much more might have been said about agriculture's debt to botanical research. J. R. Dymond gives succinct account of the growth and recent developments in zoology and stresses the happy relations which exist to-day between university and Government laboratories. University biologists derive great benefit from opportunity to work in biological stations during the summer months.

The piecemeal effect, although unavoidable in a book of this kind, is a defect in connexion with the natural sciences, for their development really should be one connected story. It was the observations of pioneers and explorers which laid the foundation on which were built the detailed studies of the present day. It is a long story which starts in a note-book about unexplored country and ends in the modern laboratories of a great Dominion.

The history of medicine is treated in two chapters—Canadian medicine and biology under the French regime, by L. E. Pariseau, and medical practice under the British regime, described by J. J. Heagerty. Events of those early days make interesting reading, but little is said of recent medical work or the development of the medical schools.

The last three chapters cover astronomy, mathematics and physics respectively. W. E. Harper's clear account of astronomical work is interesting. Canada has reason to be proud of the enterprise which has given her the two great telescopes, one at Victoria and one on the outskirts of Toronto. Important and original work has been done at the observatories. The chapter on mathematics is

somewhat weak. The author writes rather as one defending the subject than as an historian of its progress, and too much emphasis is given to minor work. In the concluding chapter, on the advance of physics in Canada, A. N. Shaw gives a good general survey, outlining the present work in physics and the date of establishing laboratories, etc., at each of the Canadian universities. He points out the influence of the Cavendish Laboratory at which so many of the Canadian physicists have been trained. The history of physics in Canada is, of course, bound up with that of the late Lord Rutherford who in his ten years at McGill gave such a profound impulse to physics in the Dominion. The writer says: "Undoubtedly Lord Rutherford may claim sole responsibility for the greatest outburst of original research in Canada and the subsequent influence of his personality and works is beyond assessment."

T. ALTY.

UNIVERSAL ALGEBRA

The Calculus of Extension

By Prof. Henry George Forder, including Examples by Robert William Genese. Pp. xvi+490. (Cambridge: At the University Press, 1941.) 30s. net.

ABOUT a hundred years ago, when Boole and Hamilton were extending algebra by symbolizing logical and physical entities, a similar but independent investigation was begun in Germany by Grassmann. Unlike the quaternions of Hamilton, which aroused considerable interest and became very well known, the calculus of extensive magnitudes of Grassmann attracted very little attention until the close of the nineteenth century. The appearance of Whitehead's "Universal Algebra" first made this theory well known to English readers, and the book still remains a classic, by providing an interesting and readable approach to the philosophy both of Boolean and Grassmannian algebra. The aim of the work now under review is to give a more detailed account of Grassmann's methods, and particularly to exhibit their power in all forms of geometry, metrical, kinematical and projective. The book is the outcome of many years experience and appreciation of the methods: it was begun twelve years ago as a result of perusing some mathematical notes on Grassmann left by the late Prof. Genese, and its publication has tarried through no fault of the author. The book, which goes far beyond the scope of the original notes, is full of information, and shows very clearly the power of the method and its surprisingly wide range of applications.

The calculus of extension is a form of non-commutative algebra which includes and absorbs ordinary vector theory. It can be developed in the abstract, and then applied, by means of its wealth of identities, to concrete problems in the theory of determinants, in nearly all forms of geometry, and in physics. In this respect it resembles analytical geometry, where the same algebraic form may represent at one time the locus of a point, and at another time the envelope of a line, according to the interpretation of the variables. This capacity for varied geometrical usage is, however, considerably greater in Grassmann's algebra than in co-ordinate geometry. It differs from the latter in discarding as unnecessary a co-ordinate frame of reference; and in this respect it returns to the earliest traditions of geometry.

The chapters run as follows: (i) Plane geometry, preceded by a page of bare axiomatic statements on extensive magnitudes, immediately interpreted as points and vectors. This leads to the use of similarity operators which provide neat proofs of remarkable theorems such as the Cayley Clifford problem of three-bar motion; (ii) Geometry of three dimensions, including spherical trigonometry; (iii) More axiomatic statements leading to projective geometry, where the richness of the method begins to be manifest: (iv) The theory of screws and the linear complex; (v) Differentiation and motion; (vi) Projective transformations. In Chapters vii–xv we have the general theory for any number of dimensions, including a discussion on matrices, and applications to quadrics in general, to circles, spheres and spherical 'spreads'. The final chapter, which bears on canonical forms, deals with the theory of algebraic products, recently developed by Müller, one of the chief exponents of Grassmann on the Continent.

The book is written most carefully and consistently; and it is evident that the author appreciates the value of a simple notation as an aid to thought. But it is doubtful whether the unfamiliar capital Gothic type for matrices is a happy choice in a work which seeks to persuade the reader to adopt a new outlook and new methods. The author endorses the motto adopted from Leibniz by Grassmann: *etsi omnis methodus licita est, tamen non omnis expedit.* It is surprising that a method of algebraic geometry can be pursued through so long a book without the mention of invariants and with the briefest allusion to the theory of groups. Nevertheless algebraists and geometers will find the book stimulating.

H. W. TURNBULL.

Textbook of Light.
By Dr. R. Wallace Stewart and Prof. John Satterly. Seventh edition, revised by Prof. C. T. Archer. Pp. vii+365. (London: University Tutorial Press, Ltd., 1941.) 7s. 6d.

IT is not an easy task to set about revising a well-known book, since the characteristic features must be preserved, and yet the contents must be brought into line with modern development. This task has, however, been successfully accomplished by Prof. Archer in the revised version of Stewart and Satterly's "Textbook of Light". The book contains a treatment of the elements of geometrical optics of a fairly wide scope, and the mathematics is easily within the compass of Intermediate Science students for whom the book is intended; the methods of the calculus, however, might surely have been used, especially in certain cases.

In connexion with a book of such merit as this, one hesitates to offer any criticism, however slight, but two topics may be mentioned. Thus the use of pins for experimental work on mirrors and lenses is still retained, although it is probably much more convincing for students to use narrow parallel pencils of light; such procedure also saves time in experimental work. Again, so painstaking is the author to drive home facts that there is a tendency for over-emphasis; for example, having established the relationship $\frac{1}{v}+\frac{1}{u}=\frac{1}{f}$ for mirrors, why trouble to express this result in words?

The book has been brought up to date (though one misses any reference to photo-electric methods in photometry), and it can certainly be recommended.

The Practical Application of Aluminium Bronze
By C. H. Meigh. Pp. xiii+112. (London and New York: McGraw-Hill Publishing Co., Ltd., 1941.) 17s. 6d.

THE alloys of copper with aluminium, with or without the addition of manganese, iron, or nickel, are commonly known as aluminium bronze. They have a high tensile strength and other good mechanical properties, and are highly resistant to corrosion. The handsome French franc and 2-franc pieces of this alloy, which had the appearance of gold and retained their colour permanently, will be remembered. Trouble owing to the entanglement of particles of alumina long retarded the general use of the alloys, but these difficulties have been overcome, and the advantages of the material can be fully utilized.

This book contains a number of practical notes on the composition and properties of the group of alloys, and detailed accounts of foundry and workshop practice, which will be found useful by all who have to make or work aluminium bronze. It is weaker on the scientific side, the accounts of crystal structure and of such phenomena as fatigue being marred by numerous errors. The tables at the end of the book include comparisons with steel and with brass and bronze, but the important high-tensile brasses are not included, although the comparison with them would have been fairer.

The term "de-aluminification" is not to be welcomed as an addition to the language, and is unnecessary.

There are some good illustrations of castings in aluminium bronze. C. H. D.

Higher Chemical Calculations
By A. J. Mee. Pp. viii+184. (London: J. M. Dent and Sons, Ltd., 1940.) 5s.

THIS book provides about 600 numerical problems on the principles of physical chemistry (including analyses) up to the standard of the Intermediate B.Sc. examination. Some of the examples are taken from the Higher Certificate, First M.B., Intermediate B.Sc. and University Open Scholarship examinations, but the majority are either original or taken from the researches which have laid the foundations of physical chemistry. The answers to these problems are given at the end of the book, together with logarithm tables and a useful index.

The subject-matter is well arranged. Thus the principles underlying the calculations are classified into ten main groups each of which forms the basis of a complete chapter. Clear and concise details of the principles are provided, and these are illustrated by worked-out examples so that the student can become familiar with the application of the principle before attempting the problems. The worked-out examples are generally satisfactory, but it is unfortunate that the answers to some of them are given to a greater number of significant figures than the measurements. Obsolete and misleading problems on the degree of dissociation and ionization of strong electrolytes are also worked out or given for solution; for example, sodium nitrate is calculated to be "63·3 per cent ionised" from the freezing point of its aqueous solution (p. 122). Apart from these criticisms, the book can be recommended for the use of sixth-form pupils and first-year university students.

A. C. C.

British Water Beetles
By Frank Balfour-Browne. Vol. 1. (Ray Society Vol. 127 for 1939.) Pp. xx+376+5 plates. (London: Bernard Quaritch, Ltd., 1940.) 25s.

AQUATIC Coleoptera have long been favourite objects of study, especially by the biologist and the physiologist. Dytiscus, Gyrinus and Hydrophilus, for example, have alone attracted the attention of many investigators and a bibliography of their written contributions on these creatures would fill many printed pages. The present volume deals with members of the Haliplidæ, Hygrobiidæ and part of the Dytiscidæ. It is concerned more especially with the habits and distribution of their species and is not intended as a systematic treatise. It will be noted that keys, therefore, take the place of detailed descriptions as aids to the identification of the various species. Prof. Balfour-Browne has devoted many years to the study of water beetles and is probably better qualified than anyone else in England to describe their natural history and where to find them. Coleopterists will welcome the appearance of this well-produced volume and look forward to the completion of the work when circumstances permit.

CHANGES IN THE GOVERNMENT OF INDIA

By Sir Denys Bray, K.C.S.I., K.C.I.E., C.B.E.
Formerly, Foreign Secretary, Government of India

On July 22 the Viceroy of India made an announcement that came as a great relief to many in Great Britain who had been chafing under our apparent inability to do anything to relieve the political deadlock in India. It was a notable announcement; yet its wording was studiously matter-of-fact. It merely stated that as a result of the increased pressure of work in connexion with the War it had been decided to enlarge the Executive Council of the Governor-General of India, and to establish a National Defence Council in order to associate Indian non-official opinion so far as possible with the prosecution of the war; and then followed the names of seven Indians who were to join the former and of twenty Indians who (with two non-Indians) were to represent British India on the latter.

To those in Great Britain with no knowledge of the working of the Government of India, the Viceroy's announcement can have conveyed little of its true significance. When Mr. Amery in a weighty speech expounded these changes in the House of Commons, his statement was received with calm satisfaction, tempered only by expressions of regret that they did not go further. The House seemed scarcely conscious that anything out of the way had been enacted; indeed the Secretary of State was at pains to emphasize that the changes involved no alteration in the constitution but were merely administrative changes, interim measures taken within the existing framework. Yet it may be doubted whether these changes will not figure in history as in some ways an even more significant milestone on India's road to full nationhood than the great constitutional change embodied in the Government of India Act of 1935 after months of heated debate. For that Act, while it brought self-government to the eleven Provinces of British India, left the Central Government for the time being untouched. But the changes now so modestly introduced affect the working of the Central Government itself.

For the Viceroy's Council is no mere advisory body. In the Governor-General in Council, to use the technical term, is vested the supreme authority in India. The Council is in fact a Cabinet with collective work and responsibility, composed of Ministers—or Members as they are called—each in control of one of the great Government departments, the Viceroy himself being member for foreign affairs. During the first fifty years of its being the Council was purely British in composition. Not until 1909 was an Indian appointed; not until 1920 was the number of Indians raised to three; and now the Viceroy is to preside over a Cabinet with Indians in a majority of two to one. It is a transformation that would have made Lord Curzon stare and gasp. That it evoked not a word of dissent in Parliament (except on the score that it did not go far enough) and scarcely a word of criticism in the Press is significant of the wholesale and very wholesome change that in half a dozen years has come over political thought in Great Britain. It is to be hoped that a very full report of the debate and the subsequent Press comments was telegraphed to India. The warm-hearted spirit in which the changes have been welcomed in Great Britain is likely to prove more acceptable to political India than the changes themselves.

No one with any knowledge of the political currents in India to-day could be so sanguine as to expect a general welcome from India for any changes which do not involve a formal change in the constitution. We in Great Britain pride ourselves on the vitality and unseen growth of our own unwritten constitution, and are inclined to eye written constitutions not a little impatiently—if indeed we can bring ourselves to study them at all—and to judge them not by the written letter but solely by the spirit in which they are worked. Naturally enough, it is otherwise with Indians. Accustomed as they are to a written constitution, they look jealously at every letter in it, and are apt to assume that the checks and safeguards every written constitution must perforce contain are a faithful reflex of its everyday working. Though the present changes, as Mr. Amery told the House, are a signal "earnest of our desire to transfer to Indian hands a steadily increasing share in the control of India's destiny", they are interim adjustments only, pending the day when Indians are able to accept our invitation "by agreement among themselves to devise the framework of the Indian constitution in accordance with the social, economic and political structure of Indian life". The changes mark an abiding and far-reaching change in the spirit of the constitution; and it is history's lesson that in the life of a nation it is the spirit that quickens. But great though the change in the spirit, the letter of the constitution remains unchanged. The Governor-

General in Council, though the supreme authority in India, is still responsible to the Secretary of State for India and ultimately to Parliament. However responsive the Council may be to the Indian Assembly—and with Indians in an overwhelming majority it is a foregone conclusion that its responsiveness will be very sensibly quickened—its members are not responsible to it; nor can the Assembly turn them out of office. Hence, with the constitution left unaltered, the All India Congress declined to have anything to do with these interim measures or to allow its adherents to join the Council. The Muslim League, though glad enough that the constitution has been left for the time being as it is, laid down conditions for its own participation too exacting for acceptance.

It is, of course, a misfortune for India and for the British Commonwealth that neither of the two leading parties is formally represented on the Executive Council. Yet the Council will contain men who, abating nothing of their robust nationalist patriotism, have only dissociated themselves from their party over the non-constructive tactics it is pursuing. Happily, India has no dearth of public men of ability; and among the new members—of whom three are Hindus, bringing the number of Hindus on the Council to four, three are Muslims and one a Parsee—are men who have made their mark in India, and are not unknown in Great Britain and in the United States and at Geneva. Together they form a strong reinforcement to the Council.

How well off India is for public men may be seen from the names in the long list of appointments to the National Defence Council. This is an entirely new body. Unlike the Viceroy's Council it is not an executive but an advisory body, designed to bring the war effort in the Provinces and States into more direct and effective touch with the Central Government. Except for one representative of European commerce and another of the resident Anglo-Indian community, it is purely Indian in composition. It includes the Prime Ministers of four of the Provinces, representatives of labour, capital and agriculture, and well-tried champions of the depressed classes. Perhaps its most striking feature is the inclusion of a gifted Muslim lady—a wise appointment justified by a fine record of public service, and a fitting recognition of the swift and splendid awakening of India's womanhood.

These representatives of British India are to be joined on the Defence Council by representatives of the Indian States—that vast Indian India which, though an integral part of India, is not British India at all but under the rule of hereditary chiefs and princes. Who can doubt that India's war effort, already far greater than any one could have prophesied two years ago, will rapidly increase in vigour and magnitude, now that some of the best minds in the Provinces and the Indian States are to combine in a joint endeavour to stimulate it?

But the strengthening of the Central Government and the intensification of India's war effort are not all that may be looked for from this influx of Indians into the Viceroy's Council and this gathering of Indians from Provinces and States in a National Defence Council. It is not too sanguine to hope that these innovations will help to prepare the ground for the even more difficult task of constitution-building that lies ahead of India. To-day what stands in the way of India's self-government and evolution to her full status is, as Mr. Amery put it, "the absence of any willingness among Indians themselves to agree upon the lines on which they will govern themselves". Hitherto the rock of stumbling has been India's intolerance of her own diversity. But we in Britain have learnt that there is nothing like joint work for a supreme cause in a supreme crisis to bring about understanding of our political opponents, tolerance of their views, and a silent revolution in our own; and Executive Council and Defence Council alike will afford such joint work in plenty.

The characteristics of English-speaking peoples—and political India, be it remembered, is an English-speaking people—were summed up in memorable words by a statesman speaking in London a few weeks ago. "English-speaking countries are peopled by men and women of diverse nationalities and different religions. Their strength comes from diversity, and their freedom is born of tolerance—tolerance of other people's origins, other people's religions, other people's ideas. It is the crowning virtue of English-speaking countries that they recognize and respect virtue wherever they find it, and are not inclined to beguile themselves with a primitive and barbaric idea that they themselves have a monopoly of it."

These are the words of one whom many Indians in the ranks both of labour and capital know well. They are not the words of an Englishman. They are the words of the late head of the International Labour Office, now the American Ambassador in London. No words could better sum up the spirit in which all lovers of India long to see political India set itself to the task of working out India's salvation. The future of India, that great cosmos of nations, cannot lie in any one race or religion or party claiming for itself the monopoly of political wisdom and authority. India's salvation can only lie in the Indian's tolerance of other Indians' origins, religions, ideas. In India's rich diversity, in India's triumphant unity in diversity lies—who can doubt it?—her future strength.

THE PRICKLY-PEAR PROBLEM IN AUSTRALIA

By Dr. A. D. Imms, F.R.S.

THE entry of the prickly-pear into Australia dates from about 1787, when the species *Opuntia monacantha* was introduced from Rio de Janeiro. The object was to establish the cochineal industry in that land since prickly-pears constitute the host for this particular kind of insect. Some twenty-five other species of Opuntia have found their way into Australia, but their origins cannot be traced. All have become naturalized either as serious pests, minor pests or as garden escapes. The two major pest species in Australia are *Opuntia inermis* and *O. stricta*. At one time landowners grew hedges of prickly-pear around their homesteads until they got out of hand and then the hedges were cut down. The rapidity with which these pests have increased is one of the botanical wonders of the world. Their original home is the coastal sector of Texas and Florida where the mean rainfall is 40–50 in. Yet in Australia the plants have adapted themselves to a very different environment and with a precipitation of only 20–30 in. annually. In 1900 an area of about 10,000,000 acres was affected in Queensland and New South Wales. The invasion advanced with such celerity that at the peak, in 1925, the affected area must have been greater than 60,000,000 acres : in some years the annual increase in infested territory exceeded 2,500,000 acres. The main distribution takes place by seeds, but every broken-off segment of the plant is liable to take root.

The problem of the control and eradication of the pest has been a matter of cost. The great bulk of the infested territory, stretching 900 miles between lat. 20° S. at Mackay, Queensland, to lat. 33° S. at Newcastle, N.S.W., is natural grazing land generally worth less than £1 per acre. Biological control of prickly-pear was first advocated in Australia in 1899. In 1912 the Queensland Government appointed a Travelling Commission to investigate possibilities of biological control in view of the increasing difficulties facing mechanical and chemical methods of eradication. The Commission comprised Dr. T. Harvey Johnston, professor of biology at the University of Queensland, and Mr. Henry Tryon, Government Entomologist to the State. They visited many countries where prickly-pears were indigenous or had become acclimatized and made valuable recommendations for the introduction of insects and diseases affecting Cactaceæ. During these travels small stocks of the cochineals, *Dactylopius ceylonicus* and *D. greenii*, were forwarded to Australia. The first-named was liberated in the field and in a few years it almost completely eradicated *Opuntia monacantha* and this achievement gave a stimulus to efforts in biological control.

In 1920 the Commonwealth Prickly Pear Board came into being with Prof. T. Harvey Johnston as scientific controller. It was established to investigate the whole question of the biological control of prickly-pear, being supported by the Commonwealth Advisory Council of Science and Industry and by the Governments of Queensland and New South Wales. Mr. Alan P. Dodd's report* is an official record of the campaign and its progress from the Board's inception in 1920 up to the year 1940. The Board, it may be added, has been an independent body from its start, exercising complete control over its investigations, finances and staff. During the nineteen-year period June 1920 to May 1939 the sums actually spent on prickly-pear control amounted approximately to £168,600.

The operations of the Board were governed by the fact that in America insects, diseases and other agencies keep the prickly-pear within reasonable bounds, whereas in Australia such natural controlling agencies are wanting and there is little check on the spread and reproduction of the pest. The Prickly Pear Board was concerned with an attempt to bring about a condition of biological equilibrium by the introduction of insects and diseases likely to provide natural checks. The control aimed at depended upon the introduction of a complex of organisms working collectively in destructive unison. Officers of the Board studied insects affecting Opuntia in many lands, covering widespread areas of cactus growth in North America, South America and the West Indies. In work of this character it is important to study on the spot, not only those insects actually attacking prickly-pear, but also the natural parasites and predators affecting them. The exclusion of such restraining agents from Australia, if their hosts are to multiply freely and vigorously attack the prickly-pear in the new surroundings, is of prime importance.

The Board established a station at Uvalde, Texas, where extensive preliminary biological work has been carried out and the most promising cactus-feeding insects bred under caged conditions. Also, such insects were tested by starvation and other means regarding the possibilities of their attacking cultivated plants of economic value. The selected

* The Biological Campaign against Prickly-Pear. By Alan P. Dodd. Published under the authority of the Commonwealth Prickly Pear Board. Pp. iv+177+37 plates. (Brisbane: Government Printer, 1940.)

Fig. 1.
DENSE PRICKLY-PEAR, *Opuntia inermis*, PRIOR TO ATTACK BY INSECTS, CHINCHILLA, QUEENSLAND, OCTOBER 1926.

species received from America were shipped to quarantine buildings at Sherwood, near Brisbane. Here they were again bred through one or more generations in order to preclude the escape of any parasites that might have been accidentally introduced at the same time. Also, additional tests were undertaken in order further to explore any possibility that the introduced insects might attack crops or other useful plants and not confine their activities to prickly-pear. From Sherwood, species that were deemed promising and that had withstood the foregoing testing, were eventually forwarded to acclimatizing and breeding centres where the first liberations into the open country were usually carried out.

In all, twelve species of prickly-pear insects were introduced and established in Australia. On the other hand, 150 species of cactus-feeding insects were discovered in America and of these about 50 species were imported into Australia. It will be noted that the greater number were rejected for various reasons. Many were confined to cacti other than Opuntia ; others caused too little damage to be of potential value, while some forms were discarded because they did not pass the stringent tests as regards their feeding propensities. Lastly, the unexpected and overwhelming success attending the introduction of a single species of insect rendered further importations of other kinds superfluous.

Of the various species that have become acclimatized to Australian conditions the moth *Cactoblastis cactorum*, the larvæ of which tunnel through the tissues, is the most important. The cochineal became distributed almost everywhere in the prickly-pear country and the plant-sucking bug, *Chelinidea tubulata*, spread in countless millions over various localities. The red spider, *Tetranychus opuntiæ*, said to be only a biological race of the European *T. telarius*, also spread over many thousands of square miles. In his 1929 report Dodd stated that the established complex of insect enemies was already bringing about a considerable degree of prickly-pear control. In the heart of the infested country it was possible to travel for 100 miles without seeing any healthy plants. Thus it would appear that the original conception of a biological association of different enemies working in unison was well justified. It was quite unforeseen, and could not have been foreseen, that the outstanding success in the repression of prickly-pear achieved up to 1936 would have resulted from the activities of a single species of insect. The agent in question is the Phycitid moth, *Cactoblastis cactorum*, from South America. This fact is all the more remarkable because only one small consignment of material was introduced into Australia. It took the form of about 2,750 eggs obtained in the Argentine in March 1935 and, a year later, two generations of this insect had been reared in captivity, the original number multiplying to 2,540,000. Between 1928 and 1930 about three thousand million eggs, laid by the descendants of insects from the original batch, were distributed in the prickly-pear areas. The

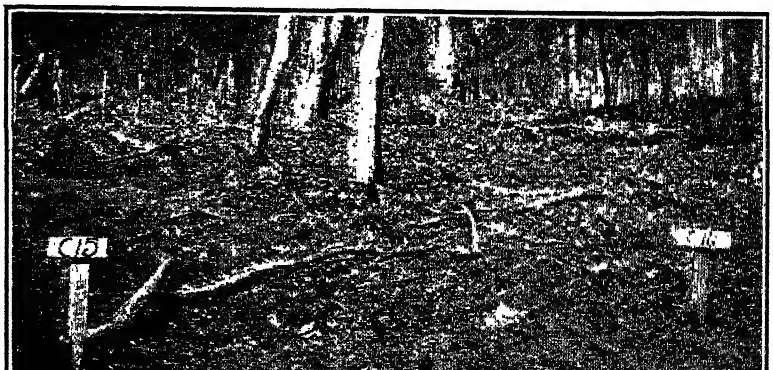

Fig. 2.
THE SAME AREA AS IN FIG. 1 THREE YEARS LATER, OCTOBER 1929, AS A RESULT OF THE ONSLAUGHT OF CACTOBLASTIS.

orange-red larvæ are gregarious internal feeders, which tunnel in companies through the tissues of the plant, thus providing also for the ingress of disease organisms. In this manner the prickly-pear ultimately becomes so completely destroyed that it is reduced to a rotting mass of pulp.

The various other insects that were established have either become suppressed, or their activities nullified, owing to competition with the Cactoblastis. It is only locally, and in relation to a few Opuntia species of minor importance, that the Cactoblastis has shown itself to be ineffective. The most serious of these plants is *Opuntia aurantiaca*, but there is good reason to believe that its control by a species of Dactylopius (cochineal), also from the Argentine, seems assured.

The results of the repression programme have led to 22,000,000 acres of former dense pear country in Queensland being selected for settlement. The previous value of this land was almost nothing, but freed from the pest its capital value would average 10*s*. an acre, without taking into consideration the worth of the new improvements in fencing, water facilities, removal of timber, etc. Hence the State has gained an asset of at least £10,000,000 because of the availability for farming of land hitherto useless. The area once under impenetrable prickly-pears, and now converted to dairy pastures, must exceed 1,000,000 acres on which many hundreds of new settlers live. In New South Wales the greater part of the former prickly-pear country has been brought into production, mainly for sheep grazing, and most of it has been utilized to enlarge adjacent pastoral properties.

The present status of Cactoblastis is satisfactory. Concentrated numbers of larvæ are still attacking, reducing and destroying many of the remaining prickly-pear areas of heavier growth. Native parasitic Hymenoptera are not exercising an undue amount of control and their importance is not growing. After an interesting discussion of the future of the problem, Mr. Dodd concludes that, up to date, there is no indication that prickly-pear will not continue to be held in complete subjugation by its remarkably efficient lepidopterous enemy.

THUNDERSTORM PROBLEMS

By Dr. F. J. W. Whipple

On July 20 the London Branch of the Institute of Physics visited the Royal Meteorological Society at South Kensington to take part in a discussion on "Thunderstorm Problems". Sir George Simpson, president of the Royal Meteorological Society, was in the chair—a happy arrangement, for Sir George has been working at thunderstorms for nearly forty years; his classical work in India, which included the experiments on which the breaking-drop theory of the production of electricity is based, was published so long ago as 1909 and his most recent papers on the subject describe work of equal importance.

The discussion was opened by Dr. T. E. Allibone, who spoke on "The Physics of Lightning". His survey began with the year 1889, when Vernon Boys told the Physical Society that a lightning flash consisted of many separate strokes traversing the same path. Later, Hoffert recorded eight strokes on a photographic plate by waggling the camera about a vertical axis, and Walter, by using a camera mounted on a turn-table, was able to show that the strokes might be spread over a period of a second. It was Boys again who constructed a camera incorporating two identical lenses rotating about a common axis. The two images of a flash photographed with this camera were distorted differently and, the rate of rotation of the lenses being known, the speed with which the flash had developed could be determined. The Boys camera has been used effectively by Schonland in his studies of storms in the neighbourhood of Johannesburg.

Schonland and his collaborators demonstrated that a lightning flash to earth is a very complicated phenomenon. There is a preliminary 'leader' which starts from the cloud and sends out a number of branches; when one of these reaches the ground it becomes the channel for the main stroke up which the luminosity travels from ground to cloud. Subsequent leaders and main strokes use the same channel. The first leader alone is branched. Its progress is by jerky steps of about 50 metres. Comparison with electrical records has shown that the current in the main stroke is a hundred or more times as strong as that in the leader stroke. The main stroke removes to the ground the charges lowered from the cloud by the leader and retained for a while as ionization in the channel. It may be noted that in detailed studies the timing of a leader is conveniently reckoned in milliseconds, that of the progress of the main stroke in microseconds, while the intervals between the strokes are a few hundredths of a second.

Schonland's work has been supplemented by that of McEachron, who photographed lightning striking the Empire State Building in New York and other lofty structures. The summit of the Empire State Building is 1,250 ft. above ground. McEachron discovered that, when such a high building is struck, there is an inversion of Schonland's initial process and a stepped leader travels upwards from the building. This leader is not followed at once by a main stroke; a dart leader from cloud to building intervenes. The subsequent strokes constituting the flash are of the normal type. At Pittsburgh, where oscillograms were taken showing the character of the lightning striking a tower 500 ft. high, it was found that the first leaders could be either upwards or downwards.

The most powerful currents in a lightning flash occur in the successive main strokes. The currents reach maxima of the order 20,000 amperes and each main stroke lowers a fraction of a coulomb of charge to the ground. This charge comes from the channel ionized by the leader, but many large quantities of electricity are brought down by continuing flow following the main strokes. The total discharge from a flash varies from two or three coulombs up to 100 or more. The most frequent value is about 20 coulombs.

Finally, Dr. Allibone sketched briefly theories which have been suggested in explanation of the jerky movement of leader strokes. He believes that laboratory experiments with camera and oscillograph may throw light on such theories. The potential gradient at which a flash can start has yet to be calculated.

The next subject to be considered, the distribution of electricity in thunderclouds, was introduced by Dr. G. D. Robinson. Until recently there were wide differences of opinion on this subject. The evidence available consisted of observations of potential gradient near the ground and of estimates of the charges brought down by lightning. The evidence was interpreted in various ways. To overcome the difficulties of the subject, it was necessary to develop some form of electrometer which could be carried by a balloon and sent up into the clouds. A suitable instrument, the alti-electrograph, was developed at Kew Observatory. The records obtained with this instrument indicate variations of the sign of the potential gradient by the alternation of the traces of a pair of points on a rotating sheet of prepared paper. Changes in magnitude of the gradient affect the width of the traces and exceptionally strong gradients may cause sparking through the paper.

The discussion, by Sir George Simpson and F. J. Scrase, of the data obtained with the alti-electrographs sent up from Kew in 1935 and 1936, led to the conclusion that in the typical summer thunderstorm of south-east England there is a concentration of positive electricity at the top of the cloud, a concentration of negative electricity lower down and another less widespread concentration of positive electricity near the base of the cloud. Further, it was noticed that the concentration of negative charge is always centred at a level at which the temperature is below the freezing-point. The evidence was clear that two processes were at work, one where the cloud held snow and hail, the other where the precipitation had taken the form of raindrops. The positive charge concentrated near the base of the cloud could be explained by the breaking of the larger raindrops in accordance with the theory propounded by Simpson himself in 1909. It was recognized that the process which was active in the upper part of the cloud was analogous to the electrification of drifting snow. Collisions of ice crystals charge the ice negatively and the air positively. It is the settling of the ice crystals through the air which separates the charges. Incidentally, it may be mentioned that C. T. R. Wilson pointed out in 1923, in the "Dictionary of Applied Physics", that "Simpson's explanation of the electrical effects of drifting snow would seem to imply that snow and hail clouds should be of positive polarity", but this remark seems to have passed unnoticed.

Recently Sir George Simpson and Dr. Robinson have given details of additional soundings at Kew. They have discussed anew the earlier evidence and cleared up various difficulties. The triple structure of the summer thundercloud may be regarded as well established. The structure of thunderclouds in other parts of the world must be very similar, but it is likely that in some regions, notably in South Africa, where Schonland finds a great preponderance of negative charge brought down by lightning, the positive charge at the bottom of a cloud is not so well developed as in England.

In his contribution to the discussion, Mr. J. F. Shipley dealt with the development of thunderstorms and with the character of the air currents in the clouds. He has found evidence for the existence inside a thundercloud of great eddies, like smoke rings with a common vertical axis. That aeronauts who have ventured in balloons into thunderclouds have experienced violent movements, downwards as well as upwards, is notorious. Occasionally a balloon has been carried up and down repeatedly through several hundred feet. This is what would have happened if the balloon had entered a great vortex ring. The same hypothesis accounts for the appearance of some hailstones, which have grown like apples or like miniature fly-wheels. These must have been rotating violently during their growth. It must be admitted, however, that there is nothing in the appearance of

most thunderclouds to suggest the presence of the vortex rings. Perhaps careful watching of accelerated motion pictures would reveal their existence.

Since the earliest days of wireless telegraphy it has been known that distant lightning affects the apparatus, and the hope has been entertained that it would be practicable to obtain direct observations which would be of use in locating storms with sufficient accuracy to meet the needs of the weather forecaster. Modern methods of recording and analysing atmospherics, the electromagnetic waves which proceed from lightning flashes, were explained to the meeting by Mr. F. E. Lutkin. The wave forms can be photographed with suitable apparatus, the horizontal movement of the light-spot of a cathode ray oscillograph being recorded on paper carried by a rapidly rotating drum. A high peripheral velocity, several metres per second, is needed.

There are a number of types of atmospheric. In the most frequent a series of oscillations with diminishing amplitude merges into a long smooth surge. The principal oscillations gradually lengthen, the first interval between peaks being of the order 150 microseconds and the fifth of the order 300 microseconds. The long surge lasts about a millisecond. The oscillatory movement is associated, it is believed, with the main stroke in a lightning flash, the long surge with the continuous discharge through the ionized channel.

In Australia and South Africa the peaks in the oscillatory movement have been related to the distance of origin by assuming each to be an echo, which has been subjected to a number of reflexions from the ionosphere and from the ground. In this way both the distance of the lightning and the effective height of the ionosphere can be determined.

The Australian and South African teams have both contended that the amplitude of the atmospherics can be used to measure the distance of origin. The approximation can only be very rough. The records at Slough show that the mean value of the field charge at the beginning of an atmospheric varies from 50 volts per metre at 25 km. to 0·1 at 5,000 km., but the individual values are well scattered about the means. A variation in the ratio of ten to one is often found in the amplitudes of atmospherics from a single source.

There are numerous applications of direction finding in the study of atmospherics. For locating storms two stations are required, preferably with telephonic communication; the various areas in which storms are taking place can be identified without difficulty and with reasonable precision.

The number of atmospherics received in Great Britain is greatest during the night in winter; 100 per second is a rate of frequent occurrence. These originate chiefly in tropical America. In summer, similar sources are indicated during the night hours and, during the day, there are large impulses, occurring less frequently, of European origin. Conditions are never favourable for the transmission to England of atmospherics from Africa, for the thunderstorms occur there in our day-time, when long waves cannot be transmitted.

A lively general discussion followed the four formal contributions. The outstanding difficulty in the whole subject is to explain how a lightning stroke begins. The idea that, owing to the existence of a large space charge, potential gradient increases from the ground up to a maximum at the base of a thundercloud, a maximum high enough to initiate a spark, has had to be abandoned. Very strong gradients, sufficient to cause sparking in the alti-electrograph, occur however inside the clouds, and this suggests that a flash to ground originates within the cloud and extends downward in the leader stroke process. The suggestion was made in the discussion that the trigger might be a spark between two drops, highly charged with electricity of opposite signs, brought together in their fall through the cloud.

Much interest was shown in the location of thunderstorms by radio apparatus, and it was stated that a practical application of the method has been found in the safeguarding of transmission lines. It is sometimes possible to cut out of circuit a line which passes through a region where thunderstorms are active, the instructions being sent from a central station with apparatus for determining the bearings of atmospherics.

As to apparatus required for further studies of thunderstorm problems, perhaps the outstanding need is for the development of simple electrographs which will serve to provide measurements of the strength of the field in and around the clouds. More than one type of electrograph is needed, for weak fields have to be measured as well as strong ones. A comparison of records of strong fields will serve for a satisfactory calibration of the alti-electrograph traces. The measurement of the weaker fields is especially desirable above the clouds. At present it is definitely known that the gradient immediately above a cloud is negative, so that an electric current starts upwards. Some of the lines of flow curve round and reach the ground at a modest distance; but it is believed that others go upwards to the ionosphere and carry electricity which is to return to earth in the air–earth current of fine weather. It is to be hoped that, some day, measurements of potential gradient and conductivity will be obtained well above the clouds and show whether there is an upward current strong enough to furnish the appropriate quota of air–earth current.

THE TOTAL SOLAR ECLIPSE OF SEPTEMBER 21, 1941

By D. H. SADLER
SUPERINTENDENT, H.M. NAUTICAL ALMANAC OFFICE

ALTHOUGH the achievements of Dr. B. Lyot in photographing the corona without an eclipse[1] have provided an alternative method for certain spectroscopic work on the inner corona, a total solar eclipse still provides the only opportunity for observation of the outer corona, and for many other important researches such as, for example, the observational determination of the deflexion of light by the mass of the sun. The total time available for observation during totality is only a few hours a century, so that literally every second is of prime importance. That the tracks of totality may pass across the earth's surface in a band 60–100 miles wide without crossing land, or be confined solely to polar regions, together with the ever-present chance of cloud, acts merely as a greater inducement to make the fullest use of every opportunity. It is thus particularly unfortunate that the shadow of war is likely to obscure the shadow of the moon on September 21.

The eclipse of September 21, 1941, may be classed as 'about average' in regard to duration of totality, accessibility of the track of totality, and likely conditions of observation. The track passes overland for half its length, starting at a point midway between the north of the Black Sea and the Caspian Sea, passing a few miles south of Astrakhan, where the eclipse is visible shortly after sunrise, with the sun only a few degrees above the horizon; it then crosses the northern portion of the Caspian Sea and proceeds across Lake Aral into Turkestan. It passes a short distance (about 200 miles) north of the Observatory at Tashkent, but the altitude will not be more than 20° and the duration less than two minutes; even so it is a 'close approach' to an established observatory. As the track passes from Russian to Chinese Turkestan it crosses mountainous country to which access would be extremely difficult. Proceeding in a south-easterly direction the track sweeps across China, emerging at the coast almost midway between Shanghai and Hong-Kong, a few miles only north of Foochow; it passes just north of Formosa. The far interior of China is probably not readily accessible for astronomical expeditions, and in any event conditions of both altitude and duration improve towards the east; the track, however, does pass over Hankow, at which place the eclipse will occur at local noon with the sun at an altitude of 62° and with a duration (the maximum for the eclipse) of 200 seconds. It is between Hankow and the coast that the best conditions for observation will probably be found. Leaving the coast of China, the belt of totality passes out into the Pacific Ocean and the remainder of the track does not strike land, except for two small islands, (Rota or Luta Island and Tinian Island) slightly north of the important island of Guam; the southern limit of the eclipse track passes about 20 miles north of Guam itself.

It is not a very common occurrence for an eclipse to be visible from an important city, situated within a few miles of the central line of totality; it is a much rarer event, and one that must be almost unique, for a city to be within 30 miles of the point at which central eclipse occurs at local apparent noon.

Although present conditions have made expeditions from Great Britain quite impossible, it is hoped that the eclipse will not pass unobserved. It is unlikely that the Russian astronomers at Tashkent will allow an eclipse almost 'on their doorstep' to pass without making some attempt to observe it; observing conditions will not be good, however, and the difficulties of transport, combined with the overshadowing war with Germany, will not encourage a full-scale expedition. At the Stockholm meeting of the International Astronomical Union in 1938, both Chinese and Japanese delegates offered to give all facilities and assistance to astronomers intending to observe the eclipse in China; unfortunately there will now be none to take advantage of these offers. It is hoped that both the Chinese and Japanese astronomers will make an effort to secure observations, but so far no reliable information is available about any proposed expeditions.

Similarly, no definite information is to hand about American expeditions, but in view of the international tension, it must be considered unlikely that any expedition will go to China; the islands to the north of Guam (Rota Island lies well within the track) would be a possible eclipse site.

This is the second eclipse that has been partially obscured by war; the enforced absence of the European astronomers from the eclipse of October 1, 1940, was compensated by the good work of the South African astronomers, who operated instruments sent from Great Britain in addition to their own.

OBITUARIES

Prof. Paul Sabatier, For.Mem.R.S.

THE recent death of Paul Sabatier at Toulouse has removed from our midst one of the founders of modern catalytic chemistry. Sabatier commenced his lifelong research into problems of catalysis in 1897. The year 1900 may be regarded as the dawn of the epoch of catalytic hydrogenation, an investigation which culminated in the award of the Nobel Prize in 1912.

While Sabatier's general method of approach was from the point of view of a preparative organic chemist, nevertheless in the course of his work he showed a deep perception and thorough appreciation of the physical chemical implications. The range of reactions which he studied both by himself and with his co-workers, among whom the Abbé Senderens must be especially singled out, is truly remarkable, and a good account of them is presented in his monumental book "La Catalyse en Chimie Organique", first published in 1913 with a second edition in 1920.

Sabatier was greatly interested in the problem of hydrogenation, and showed *inter alia* that good hydrogenating catalysts were also effective in dehydrogenation; he succeeded in the difficult case of benzene in both hydrogenating it to cyclohexane and in dehydrogenating the product on the same catalyst. In his very early experiments he observed how sensitive catalysts were to heat treatment and how active catalysts could be prepared by gentle reduction of the oxides or nitrates. The use of alcohol instead of hydrogen as a reducing agent is due to Sabatier. He has put on record many interesting cases of selective hydrogenation which still await adequate explanation, such as the reduction of $\varphi CH_2\ CH_2\ CO\ CH_2\ CH_2\varphi$ to $\omega\ \omega'$ diphenyl pentane or to dicyclohexyl pentane, or amyl acetylene to amyl ethylene or to normal heptane, the former on a 'less active' copper catalyst, the latter on an 'active' nickel catalyst.

One of Sabatier's most illuminating contributions to the science lies in his discovery of directive or selective catalysis. He showed, for example, that formic acid could undergo two modes of decomposition, to carbon dioxide and hydrogen or to carbon monoxide and water; that alcohols could be converted into aldehydes and hydrogen or to ethylene and water. While metals 'favour' the first mode of catalytic decomposition and dehydrating oxides the second, there exists a whole series of catalysts on which both reactions occur, the relative extent of each reaction being dependent on the mode of preparation of the catalyst and on the temperature. This specific action of the catalyst led Sabatier to write: "La nature chimique du catalyseur exerce une action décisive dont on peut guère trouver l'explication que dans des combinaisons temporaires quoiqu'il puisse être dans certain cas, difficile d'en précisir la vraie nature." The modern hypothesis of the intermediate chemical compound or chemisorbed complex could not be expressed more clearly. That these "combinaisons temporaires" are not identical with isolatable chemical compounds could be gathered from further work of Sabatier, who was one of the first to evaluate the exact temperature coefficient and the apparent energies of activation of catalytic reactions. In many cases these were relatively small and less than those required to decompose the true chemical compounds.

Sabatier was likewise the first to pay detailed attention to what are now termed promoters; already in 1902 he investigated the effects of incorporating various oxides, for example, of beryllium, aluminium and magnesium in a nickel catalyst to obtain more active and robust systems. Among the many and varied catalytic reactions discovered by this indefatigable worker the following may be mentioned as ones which have been adapted to modern chemical industry or are potentially important: the reactions of alcohols with hydrogen sulphide and ammonia to yield thiols and amines respectively; esterification in the gaseous phase; the formation of ketones and ethers from acids and phenols. In hydrogenation reactions we may mention the reduction of the cyanides to amines and of the isocyanides to secondary amines and the stepwise reduction of the nitro group in cyclic nitrobodies.

Doubtless many of us wish that circumstances might have permitted us to solemnize in a more formal manner the departure of Paul Sabatier to a distant shore, but we can at least affirm that he has left his imperishable characteristic imprint on our science and on our industry. ERIC K. RIDEAL.

Dr. E. L. Ince

DR. EDWARD LINDSAY INCE, head of the Department of Technical Mathematics in the University of Edinburgh, died on March 16 at the comparatively early age of forty-nine. Dr. Ince, who was one of the first research students of Prof. E. T. Whittaker when the latter established a school of mathematical research in Edinburgh almost thirty years ago, had a varied life of mathematical activity. From Edinburgh he proceeded to Trinity College, Cambridge, becoming a Smith's Prizeman during the War of 1914–18. In 1918 he was a temporary lecturer at the University of Leeds; in 1919 he studied at Paris; from 1920 until 1926 he was a lecturer in mathematics at the University of Liverpool. In 1926 he was appointed to the professorship of mathematics in the then newly founded Egyptian University in Cairo, but in 1931 he returned to Britain for the sake of the health and education of his family. For a brief period he was lecturer in the University of Edinburgh, then at the Imperial College of Science and Technology, and finally, from 1935 until his death, lecturer in technical mathematics at Edinburgh.

Ince's published work falls into three parts: some two score or more papers, mostly on Mathieu functions

and on linear differential equations with periodic coefficients; a tract on descriptive geometry and two text-books on ordinary differential equations; and a volume of tables ("Cycles of Reduced Ideals") computed for the British Association, on the Tables Committee of which he served for many years.

Ince firmly believed that theoretical solutions of problems, however abstractly elegant, were incomplete unless the mathematician either tabulated the solving functions himself or rendered them tabulable. Perusal of his papers will show that in his chosen field of research he achieved both of these objects. He regarded his research, however, as entirely subsidiary to the work of teaching and of examination. To these duties he brought a rigour of self-imposed obligation which in the end was worn as a natural discipline, until ill-health supervened.

Unversed in Ince's special domain, I will not presume to appraise his papers. That has been fitly done by his master and colleague, Prof. E. T. Whittaker, in the recent posthumous conferment of the Makdougall-Brisbane Prize, awarded to Dr. Ince by the Royal Society of Edinburgh. Perhaps a more personal reminiscence may be permitted. When the "University Series" of small text-books, published by Messrs. Oliver and Boyd, was projected some three years ago, the editors invited Dr. Ince to submit a manuscript on ordinary differential equations. Soon afterwards Dr. Ince was seized by a very debilitating illness, which laid the seeds of the later and mortal one. I at once begged him to relinquish or defer the undertaking; but I was met by a quiet yet firm refusal. The book had been sketched; its outlines were clear; during convalescence chapters would be pencilled; examples would later be added. And indeed in due course the book was completed; nor does it bear any trace of the physical weakness that attended its composition.

The quiet resolution that nerved Ince to this task, as later to the completion of his last paper on Lamé functions, gives the measure of the man. He drew this courage from sources which evoke the respect and reverence of his friends.

A. C. AITKEN.

Prof. N. S. Kurnakov

BY the death of Prof. N. S. Kurnakov on March 19, at the age of eighty, Russia has lost a pioneer physical chemist whose work and influence, great in his own country, extended far beyond its borders. His early training some sixty years ago in the St. Petersburg Mining Institute must have largely influenced the trend of his subsequent work, which was mainly concerned with the applications of the principles of the phase rule to the study of binary systems, more especially alloys and salt mixtures, and with the development of the mineral resources of Russia. Kurnakov was one of the first to devise and use recording pyrometers for the thermal study of alloys and binary mixtures generally, and he was particularly interested in the variations of viscosity and of hardness which accompany changes of composition in such systems. He founded one of the chief schools of inorganic chemistry in the U.S.S.R., and right to the end of his life was director of the Institute of General and Inorganic Chemistry of the Academy of Sciences of the U.S.S.R.

Kurnakov's work, carried through with the assistance of numerous younger collaborators, many of whom are now contributing materially both to the defence and the development of Russia, is an admirable example of the fact that the development of scientific knowledge and the growth of industrial practice are closely related and largely mutually dependent. The work and ideas embodied in his treatise "An Introduction to Physico-Chemical Analysis" enabled him to play a great part in discovering and developing the resources of the salt lakes in the Crimea and on the Caspian, the deposits of potassium and magnesium in the region between the Volga and the Emba Rivers, and the deposits of bauxite at Tikhvin, upon which the Russian production of aluminium largely depends. His concern with the exploitation of Russia's resources in platinum and other noble metals led to researches on their compounds, which in turn yielded important developments in the extraction and purification of these metals.

Though little known personally to his British colleagues, Kurnakov was greatly esteemed and honoured in the U.S.S.R.: he held the Order of the Red Banner of Labour and was very recently awarded a Stalin Prize.

H. V. A. BRISCOE.

WE regret to announce the following deaths:

Prof. E. Abelaus, formerly professor of physiology in the University of Toulouse.

Dr. R. D. Archibald, formerly senior lecturer in electrical engineering in the Royal Naval Engineering College, Keyham, on August 17.

Prof. Otfrid Foerster, formerly professor of neurology in the University of Breslau, honorary fellow of the Royal Society of Medicine, aged sixty-eight.

Dr. W. Gardiner, F.R.S., honorary fellow and formerly fellow and bursar of Clare College, lately University lecturer in botany in the University of Cambridge, on August 31, aged eighty-one.

Prof. Thomas Gibson, formerly professor of pharmacology in Queen's University, Kingston, aged seventy-six.

Mr. S. H. Horgan, a pioneer in the half-tone process for the reproduction of pictures, on August 31, aged eighty-six.

Prof. R. F. Irvine, the well-known Australian economist.

Mr. W. Macnab, C.B.E., the well-known chemical engineer, technical adviser to the Explosives Supply Department of the Ministry of Munitions during the War of 1914–18, on September 3.

Prof. A. K. M. Noyons, professor of physiology in the University of Utrecht, aged sixty-three.

Dr. Vinnie A. Pease, since 1920 micro-analyst in the U.S. Bureau of Chemistry (now the Bureau of Agricultural Chemistry and Engineering), on April 30 aged fifty-nine.

NEWS AND VIEWS

The British Association: Science and World Order

FURTHER details of the meeting of the Division of the Social and International Relations of Science of the British Association to be held during September 26–28 at the Royal Institution (NATURE of August 30, p. 251) have now been issued. The aim of the meeting is to "demonstrate the common purpose of men of science in ensuring a post-war order in which the maximum benefits of science will be secured for all people".

Mr. Winant, the American Ambassador, and M. Maisky, the Soviet Ambassador, will preside at some sessions, and others will be held under the chairmanship of Dr. Wellington Koo (Chinese Ambassador). Dr. Beneš (president of Czechoslovakia), Mr. H. G. Wells, and Sir Richard Gregory (president of the British Association). Czechoslovakia, Poland, Norway, Holland, Belgium, and France will be represented, and exiled men of science from Germany, Austria, and possibly Italy, will also take part. The meeting will seek to define the part which science can play in helping to secure the best use of the possibilities of the twentieth century and to make practical contributions to problems and their possible solution.

Atmospheric Pollution

THE annual report for the year ending March 31, 1940, on the Investigation of Atmospheric Pollution, which would normally be issued by the Department of Scientific and Industrial Research, has been replaced by a summary prepared for the information of the co-operating bodies. From this it appears that the deposit over the whole of Great Britain, as represented by the deposit gauges, has decreased. The highest total deposit measured for the year (395 tons per square mile) was in Manchester, while the lowest measured (57 tons per square mile) was at Loggerheads, Shropshire; both places, however, show smaller deposits than in the previous year. There were only three complete sets of results with automatic filters: Cardiff, Coventry and Stoke-on-Trent. These are not sufficient to provide a basis for comparison with the previous year. The average monthly suspended impurity does, however, show interesting characteristics, notably maxima, in January 1940, which it will be remembered was unusually cold. This increase in suspended impurity was no doubt due to an increase in all forms of domestic heating during the cold period despite the shortage of fuel in some districts. All three places show a sharp increase in suspended impurity in October, followed by a minimum in November, although the average temperature for that month was lower than the average for the past fifty years or so. It may be that the continuation of Summer Time until November 20, 1939, and the restriction on the combustion of fuel imposed by the fuel rationing scheme may be responsible to some extent for these minima in November.

Complete results for the measurement of the concentration of sulphur dioxide by the volumetric method were obtained from the stations at London (Beckton and Crossness), Salford and Sheffield. The averages from these stations are slightly lower than those for the previous year. The measurement of sulphur gases by the lead peroxide method does not show any unusual features. Measurements of suspended impurity by the automatic filter made in Central Park, New York City, show that New York has its purest air in the afternoon between 1 and 3 p.m., while the measurements for British cities have invariably shown that the early morning air is the cleanest. This difference is no doubt due to the greater convectional turbulence of a continental climate in the day-time, resulting in a distribution of the pollution through a greater depth of atmosphere and a corresponding reduction of concentration at ground-level. Further measurements made in Dublin by Dr. Leonard have shown an interesting correspondence between concentration of sulphur dioxide and suspended impurity, the two curves for the average monthly values showing a noticeable degree of parallelism. Automatic filter results at Leinster Lawn, Dublin, indicate a ratio of domestic to industrial pollution of 3·3 to 1 in winter and 2·3 to 1 in summer.

Luminous Plastics

IN a paper by Dr. V. E. Yarsley published in the *Electrician* of August 8, an interesting account is given of recent developments in moulding materials for practical purposes. Perhaps the application to luminous plastics is the one which has attracted the greatest public interest. Having a light switch, door handle or telephone clearly visible is of real practical value for a night emergency in war-time. The layman usually associates luminescence with phosphorus or radium, and the terms luminescence, fluorescence and phosphorescence are often misused. Those substances which convert incident radiations into visible light, and not into heat, as is more usual, are called luminescent. Those materials which emit visible radiations only during the period when the exciting radiation is impinging are said to be fluorescent. The commercial luminescent materials do not belong to the radium family. They are usually metallic sulphides, more particularly those of zinc, calcium, strontium and barium. Mixtures may be used, and in some cases increased luminosity results from the addition of minute quantities of metals.

Luminous plastics may be produced either by adding the luminous pigment directly to the moulding powder or by covering the moulded article with a suitable luminous lacquer. While the latter appears the more natural method, since it requires the relatively expensive luminous pigment only in the lacquer layer, yet there are certain advantages

gained by adding the pigment to the moulding composition. A considerable amount of research has been necessary to develop a luminous pigment sufficiently stable to withstand the stringent conditions of moulding, while at the same time care had to be taken that the pigment in no way affected the chemical stability of the plastic mass. Very considerable progress has recently been made in this direction.

An interesting range of moulded luminous plastics which appeal both to the domestic user and to A.R.P. authorities is manufactured by Roanoid, Ltd., of Glasgow. These are produced in a suitable light-coloured thermo-setting plastic and include moulded letters and numerals in $1\frac{1}{4}$ in. and 2 in. sizes, and also various fittings. Cellulose acetate sheet containing a variety of fluorescent dye-stuffs in standard sheets of 56 in. by 26 in. which can easily be cut or stamped to form displays or printed signs for shop windows, cinemas and theatres are available. The ultra-violet light used for irradiation of the plastic sheet is not harmful to the eyes, since the special 'blacklamps' of 80 and 125 watts used emit radiations which have no physiological action. It is stated that while fluorescent paints lose some of their power after a few weeks exposure, fluorescent plastic sheet showed no diminution during the period under test.

Examination of Jewels in Electric Meters

THE apparatus required to measure electric power is both expensive and requires special attention. The higher the accuracy aimed at the greater is the cost of the meter, and the time and labour that has to be devoted to it rapidly increases with the accuracy demanded. To encourage the use of electricity, the Electricity Commissioners have recently allowed the testing for low-load performance to be done at one tenth instead of one twentieth of full-load capacity. Another economy they have effected is to show that an appreciable extension of the life of jewels and pivots of electric meters can often be obtained by cleaning. An article on meter jewels, their examination, grading and reconditioning, giving the recommendations by the Meter Technical Committee of the Electricity Commissioners for overcoming the present difficulties of obtaining new jewels and pivots, appears in the *Electrical Review* of August 8.

The first method described is to use a microscope with a magnification of 40–70 diameters, the stage being fitted with a simple means of holding the jewels, coaxially with the microscope and automatically positioned with the jewel cup in focus. The chief defects to be looked for are surface cracks, appearing as sharply defined straight or curved lines (parallel if more than one) on the jewel surface, and scratches from the original polishing or acquired during transport. Jewels, after examination, are classified Grade 1 jewels, which can be used immediately; Grade 2, which can be re-surfaced, showing no defects beyond shallow central wear or slight scratches within the working surface area. A pivot end that is unpolished and of bad shape must be ground to shape and polished; it should be hemispherical and never ground to a needle point. Even very slight films of dust or grease may obscure serious defects. Boiling in an aqueous solution of sodium hydroxide followed by quick drying and a rinse in commercial alcohol is said to be beneficial.

The Solar Corona

DR. DONALD H. MENZEL has an article entitled "What is the Solar Corona?" in the *Telescope* of May–June, in which he refers specially to the researches of Bengt Edlén, of Uppsala, who has shown that coronium is chiefly iron. Nickel and calcium have also been identified, the outer electrons in all these elements being torn away. Difficulties arise in explaining how the comparatively low temperature of the sun—about 6,000° C.—can be responsible for tearing away the outer electrons, the removal of which requires a temperature of at least 100,000° C. Then again, Edlén has pointed out that the great breadth of the coronal lines suggests a very rapid movement of the atoms, and a temperature of 2,000,000° C. would be required to explain this. Conclusions of a similar nature have been reached by independent lines of investigation and various explanations have been suggested to account for the source of this high temperature. The most acceptable hypothesis is that the highly heated coronal matter is issuing in great jets from holes and cracks in the solar surface. These crevices, which are probably associated with sunspots, run far down into the hot interior, where the temperature is several million degrees.

Many problems arise as a consequence of this hypothesis. Thus it is suggested that solar prominences are formed as condensations from the corona, and the motion-picture records of active prominences corroborate this view. Thousands of miles above the solar surface prominences are observed to "materialize" and to be moving downwards. They are previously invisible because their earlier high temperatures caused them to emit radiations of an unfamiliar character. The identification of the remaining coronal lines still awaits a solution and a great mystery is the tendency of coronal matter to move in well-defined arches or streamers. A possible explanation may be found in the presence of magnetic and electric fields. It is suggested that the source of electrification of the ionosphere may be found in the X-ray energy associated with the coronal emission.

Forest Administration in Malaya

THE annual report of the Malay Forest Department for the year 1939 (Govt. Press, Kuala Lumpur, Federated Malay States, 1940) is of unusual interest. A history is given of the growth of the Department from the year 1883, when the Director of Gardens, Straits Settlement, initiated a small Department. Five years later, Mr. H. N. Ridley became director and instituted a policy of Government reservation which saved valuable forests from destruction during the rubber boom of thirty years ago. As the result

of a report on the forests by the late Mr. H. C. Hill of the India Forest Service, a Burma forest officer was appointed to the control. At present, the ten States of Malaya have each a Forest Department loosely united by a common and interchangeable staff of senior European officers and an ever-increasing body of Malays trained in the vernacular school of Kepong.

In some respects the Malay States now possess one of the most up-to-date forest departments in the Empire. That this is realized by the Government is evidenced by the recent investigation into the position of forestry and mining. Mining is one of the most important of the industries and yet the interests of the mining community tend to clash with those of agriculture and forestry. Some 10,471 square miles of the States are reserved forest (about 20 per cent of the country), yet 52·8 per cent of forest land still remains unaccounted for. Much of the reserved forest is in mountainous country. The mines are mostly concentrated in the plains. Since timber is heavy and will not bear expensive transport charges, the Forest Department wishes to develop the management of the forests which are reasonably accessible—often in the neighbourhood of existing mining tracts and into which the mining industry may wish to expand. It is recognized that the mining community takes a large amount of the produce of the forests. The problem which is now being faced is to settle, if possible for a period of years, those areas which will probably be required for the extension of mining. In this the Geological Department is affording assistance; thus allowing the Forestry Department to concentrate its works of improvement on workable, because accessible, forests which will not be liable to be expropriated at short notice. The crucial point arising out of the arrangement is the obvious recognition by the Government of Malaya of the importance of the forests to the country and its inhabitants.

Venereal Diseases in War

ACCORDING to M. Schubert (*Ven. Dis. Inform.*, 22, 327; 1941), a comparison between the incidence of venereal diseases in the Prussian Army during 1903–1913 and the four years of the War of 1914–18 showed that the average incidence was 20·4 per 1,000 during peace-time and 20·5 per 1,000 during the War. Contrary, therefore, to the widely prevalent but false assumption that the incidence of venereal diseases during that War was much higher than in peace, the difference was only very slight. The only increase which did occur was in the number of cases of syphilis. Of those infected during the War 67·5 per cent contracted their infection at home and only 32·5 per cent at the front. After demobilization of the army after the War there was a catastrophic increase in the incidence of venereal disease up to 1921–22, after which date there was a gradual decrease which in 1925–26 became increasingly noticeable and was probably due to better-regulated conditions for treatment. The decrease in the incidence of syphilis was greater than that of gonorrhœa. During the past few years chancroid has been very rarely seen in Germany. During the first nine months of the present War no increase in the incidence of venereal disease has been observed except among the troops who had been in Poland, in whom the number of syphilitic infections was low and chancroid was not found.

Health of Hong Kong

ACCORDING to Dr. Selwyn Clarke, the director of medical services, Hong Kong, in his annual report for 1939, the colony's chief health problem is the large number of Chinese refugees from the Sino-Japanese War. In July 1939 the number of persons entering the colony exceeded the number leaving it by 327,833. Many of the immigrants were destitute, ill-nourished and diseased, and the overcrowded conditions in which they lived were a most serious menace to public health. The largest number of deaths in 1939 were caused by non-tuberculous diseases of the respiratory system. Tuberculosis came next, the majority of the deaths being due to the pulmonary form. 24 per cent of 1,500 refugees whose blood was examined showed a malarial infection. There were more than 9,000 cases of beriberi, 800 cases of cholera and 3,000 of influenza during the year.

Announcements

A ROCKEFELLER Foundation grant of 25,000 dollars for research in endocrinology for five years under the direction of Dr. J. S. L. Browne, assistant professor of medicine and lecturer in pathological chemistry at McGill University, is among recent gifts to the University.

A DEPARTMENT of Radiology has recently been established in the medical faculty at McGill University under the direction of Dr. C. L. Peirce, radiologist-in-chief at the Royal Victoria Hospital, and Dr. W. L. Ritchie, director of radiology at the Montreal General Hospital.

THE National Institute of Health of the United States Public Health Service is organizing a new research unit to be called the "Unit of Gerontology", which will deal with the diseases of the aged. Further information can be obtained from Dr. Edward J. Stieglitz, Investigations in Gerontology, National Institute of Health, United States Public Health Service, Bethesda, Maryland.

ON the recommendation of the Agricultural Research Council, the following awards of one agricultural research scholarship and two studentships for research in animal health have been made by the Ministry of Agriculture and Fisheries, and the Department of Agriculture for Scotland: H. E. Davenport, of University College, Nottingham, a research scholarship in helminthology; F. Alexander, of the Royal (Dick) Veterinary College, Edinburgh, a studentship for research in animal health; A. McDiarmid, of the Royal (Dick) Veterinary college, Edinburgh, a studentship for research in animal health.

Hydrological and Biological Studies of Loch Sween

IT is now many years since I directed the attention of zoologists to the excellent facilities for marine biological research afforded by Loch Sween on the coast of Argyle. In the years before 1914 it provided a delightful centre for the activities of Glasgow students of zoology during their Easter vacation. During the early post-war years Government approval was actually obtained for the conversion of one of the hospital barges used on the rivers and canals of France and Flanders into a floating laboratory, to be used as tender to the Millport Marine Station and moored for periods in Loch Sween and other west coast lochs. These plans had, unhappily, to be cancelled when economic pressure brought about the curtailment of expenditure on scientific research during the lean post-war years.

It is accordingly of much interest to myself to read in an article by Dr. F. Gross[1] of his references to Loch Sween, and I think it well to indicate two lines of investigation which to my mind deserve special attention. The first of these is an intensive study of the hydrography of the Loch—more especially of the rise and fall in the level of its waters. During my early seasons there I naturally endeavoured to construct a time table, but found myself reduced to giving up this task in despair. Tidal behaviour in the Sound of Jura outside the Loch; the local distribution of barometric pressure; the direction of the prevalent wind: all these factors played their part, but it appeared to me there must be other unknown factors, and I found myself inclined to suspect something of the nature of a *seiche*. In this connexion I bore in mind the existence of the strongly flowing tidal currents of the Sound of Jura which form a kind of barrier across the mouths of the sea-lochs opening into it and which, in the case of Loch na Cil, widely open to the south-west, is so effective as to make that loch a useful anchorage even in a south-westerly gale.

The second line of investigation is that of the origin of the fine silt accumulating in the Loch and constituting a factor inimical to the oysters which in earlier days were so abundant. During my tenure of the chair of zoology in the University of Glasgow, I kept under observation a large aquarium tank in which grew the Canadian pondweed Elodea with a balanced animal population—pulmonate Gasteropods, fresh-water Oligochaetes, Protozoa, etc. My special interest in this tank lay in its gradual accumulation of a thick deposit of fine mud of organic origin—composed of fæcal and other debris from its animal and plant inhabitants—and the interesting problem suggests itself: Is any appreciable proportion of the fine mud of Loch Sween contributed by its rich planktonic and other fauna? Dr. Hilary Moore's important studies of the mud of the Firth of Clyde might find a profitable extension to the muddy deposits of Loch Sween and other similar highland sea-lochs.

JOHN GRAHAM KERR.

Tayvallich,
Loch Sween,
Argyll. Aug. 31.

Plankton as a Source of Food

THERE are several points which should be raised in connexion with the communication from Dr. Nicholas Polunin[1] in which the value of phytoplankton as plant manure is discussed. He suggests that the development of a rich growth of algæ in an open bucket or pan of water increases the value of this water as plant manure. It is, however, obvious that the only increase in total matter in the water is the carbon absorbed by the algæ. This carbon, incorporated in the algal cells, is of very doubtful value as plant manure. Growth of algæ in the water is dependent on the presence of dissolved nutrients, notably nitrogen and phosphorus salts, and the transformation of these into organic compounds does not increase their amount, or their value as plant manure, but rather the reverse, since the complex organic compounds must be decomposed by bacteria before the nutrients become available to the plants manured. For the purpose suggested, that is, the watering of vegetables, which are short-period crops, it would seem more important to add the nutrients in readily available form than to build up a reserve of organic matter in the soil. Furthermore, it is probable that there is a loss of nitrogen from the water during the development of the plankton, owing to the escape of gaseous nitrogen by denitrification or by the reaction between amino-nitrogen and nitrite. It is unlikely that any of the algæ capable of fixing nitrogen, (that is, members of the Cyanophyceæ) would grow in such tanks or buckets. It would therefore appear that the bucket of water constitutes a more valuable plant manure in its original state than it does after the development of a phytoplankton.

Figures which I obtained during experiments on the growth of algæ under conditions similar to those mentioned may be of interest. The vessels used were shallow tubs and glass tanks, open or with glass lids, heavily manured with the essential elements. Under summer conditions, a dense growth of Chlorococcales developed, but its dry weight was small in comparison with the amount of salts added. A tub of 100 litres capacity, to which 28 gm. of nutrient salts were added, produced a total dry weight of Chlorococcalean plankton of the order of 5 gm. in one month. No figures for the changes in total quantity of dissolved salts are available, but the following figures give an idea of the changes in nitrogen content. With ammonium nitrate, the decrease in ammonia and nitrate nitrogen was compensated by the increase in organic nitrogen, but in water manured with ammonium sulphate, a decrease of 15 per cent or more in total nitrogen was observed, while with potassium nitrate the decrease was 10 per cent.

It will be evident from this that the increase in humus content, which is in any event of problematical value as plant manure, is more than offset by the probable loss of nitrogen, and the certain decrease in availability of the nutrient salts.

Isolated Nerve-Muscle Junction

A SINGLE muscle fibre with its nerve supply (Fig. 1) has been dissected from the M. adductor longus of the frog (*Hyla aurea*). This preparation survives for as long as twenty-four hours at a temperature of 18–20° C., and electric potential changes have been recorded from some twenty of these isolated nerve-muscle junctions during activity. In most experiments the muscle fibre was kept in saline at a paraffin interface while the nerve was lifted into the paraffin and stimulated there. A 50-μ diameter platinum wire served as leading electrode at the junction and was insulated except where it made contact with the muscle fibre. It was moved to different positions along the muscle fibre by means of a micrometer adjustment. The second leading electrode was in the saline below the fibre and acted thus as a diffuse lead.

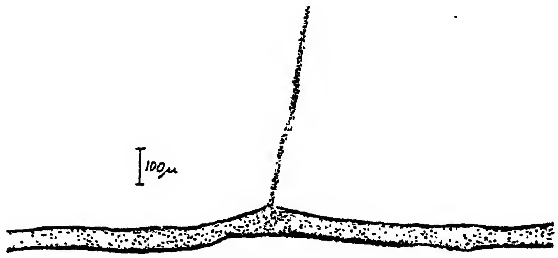

Fig. 1.

PHOTOMICROGRAPH OF A SINGLE MUSCLE FIBRE WITH NERVE SUPPLY.

A single stimulus to the nerve gives a propagated spike along the whole muscle accompanied by a contraction. Fig. 2*a* shows an action potential 0·23 mm. away from the nerve entry. Two components of the rising phase are seen; the larger and steeper one *s*, the muscle spike, which stays constant along the whole length of the muscle fibre, and an initial smaller component ε, which is only recorded near the motor end-plate (the end-plate-potential (e.p.p.), cf. Eccles, Katz and Kuffler[1]). At 150μ nearer the nerve entry (Fig. 2*b*) the e.p.p. rises much more steeply, reaching about 65 per cent of the action potential before the spike appears. With a further shift of 80μ to the nerve entry (Fig. 2*c*) the e.p.p. is so large that the spike component is barely seen rising above it. Indeed by careful adjustment the e.p.p. becomes so large that no phase of spike rise is observed. Curarization (Fig. 2*d*) diminishes the e.p.p. and the spike is delayed but not altered appreciably in total height. Below a critical e.p.p. height (Fig. 2*e*) no spike is set up and the e.p.p. alone is recorded.

Thus it can be shown that a nerve impulse gives rise at the nerve-muscle junction to a localized negative potential change as large as the muscle spike potential. This potential, in its turn, sets up the muscle spike. It decrements rapidly along the fibre and falls to about 20 per cent at a distance of 0·25–0·35 mm. from the neuro-muscular junction.

Early in the refractory period, a second nerve impulse sets up only an e.p.p. (similar to the e.p.p. in Fig. 2*e*); when later, a second muscle impulse is also set up but usually does not reach its full size until 0·5–0·8 mm. from the neuro-muscular junction. At times this impulse dies out after it has reached up to 30–40 per cent of the full spike potential and has propagated as far as 0·3–0·5 mm.

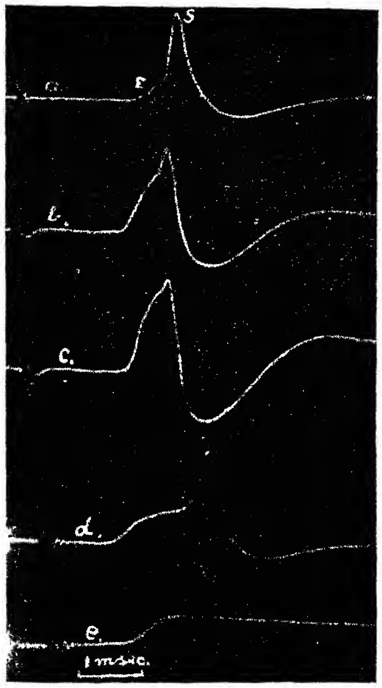

Fig. 2.

ACTION POTENTIALS. (*a*), 200μ AND (*b*) 80μ AWAY FROM THE NERVE-MUSCLE JUNCTION; (*c*) AT THE NERVE-MUSCLE JUNCTION; (*d*) SUBPARALYTIC DOSE OF CURARINE; (*e*) PARALYTIC DOSE OF CURARINE.

When recording in paraffin oil, action potentials up to 55 mv. have been obtained.

Effective and Ineffective Association between Root-Nodule Bacteria and the Host Plant

IN a recent paper, Chen, Nicol and Thornton[1] present results from which they conclude that "the production as a result of infection of soluble substances affecting the growth of the bacteria affords an explanation of those differences in nodule growth that determine the effectiveness or ineffectiveness of the different strains of bacteria as regards nitrogen fixation within the host".

A closer examination of the data given in the paper fails to confirm the validity of this conclusion. Controls do not seem to have been adequate, and there is no information as to the nutrients supplied in the plant juices which were added to such a high concentration (18 per cent). These omissions are the more surprising since the authors, in explaining the variable nature of their results, state:

"Composition of the root juice is liable to be affected by the growing conditions of the plant and by details in the method of extraction and filtration that are very difficult to control."

Briefly, three levels of growths were obtained in the

majority of experiments. corresponding with the following conditions and in this decreasing order :

(1) Basal medium + juice of effectively nodulated root;
(2) Basal medium + juice of uninoculated root;
(3) Basal medium + juice of ineffectively nodulated root.

However, there is no evidence to show that the nutritive substances of the yeast sucrose medium were such as to support maximum growth, namely, growth which could not be improved by extra nutrients in the medium. In fact, the one experiment which reports results with water instead of plant juices showed that the latter, even from poorly nourished uninoculated plants, caused considerable increase in growth :

	Mean Colony Areas (sq. mm.)	
	Without root juices	With juices from uninoculated plants
Mean growth, all strains	99·7	137·3

The possibility remains, therefore, that the stimulation in (1) over (2) is nothing more than the effect of an abundant nutritive supplement : a result of the effective association and not its cause.

The superior growth made in (2) compared with (3) might, at first glance, argue a case for inhibitory substances produced by the ineffective association. However, in the one comparison reported the growth in the medium containing the "ineffective" juice was no worse than that on unsupplemented medium. On theoretical grounds, it seems not unreasonable to expect the juices from roots carrying an ineffective strain to be relatively impoverished even in comparison with uninoculated controls. The parasitic organisms might well have tied up in their bodies the small amount of nutrients which would have been otherwise available to the cultivated bacteria. Again it is possible to regard the observed effect as a result and not the cause of the nature of the association.

It would seem then that, whilst the results presented in the paper are compatible with the hypothesis postulated by the authors, they do not offer sound evidence in support. At the most they seem to have shown that the root juice of an effectively nodulated plant is a better nutrient than that of an impoverished control which is, in turn, better than that of a plant the nutrients of which have already been largely utilized by parasitic bacteria.

J. M. VINCENT.

School of Agriculture,
University of Sydney,
Australia.

Proc. Roy. Soc., B, **129**, 475 (1940).

MR. VINCENT, who courteously sent me a copy of this letter before publication, suggests that the juice from roots bearing effective nodules is more stimulating to the growth of Rhizobium as a result of effective association. This is in agreement with our views. We state in our paper[1] (p. 489) that there is evidence of "an increased stimulating effect from juices of roots bearing effective nodules, possibly connected with the products of nitrogen fixation".

Mr. Vincent makes the further interesting suggestion that the poor growth of Rhizobium on medium containing juice from plants having ineffective nodules is in reality a deficiency effect, due to the removal by the bacteria in the nodule of nutrients present in the juice of uninoculated roots. The basal medium was supplied with mineral salts and carbohydrates in amounts shown by cultural tests to be in excess of the bacterial needs. Thus the stimulating action of juice from uninoculated roots was probably due either to nitrogen or to accessory growth substances. The following data were obtained from a pot experiment in which soy beans were grown in sand under conditions similar to those used to obtain the material for our root juice experiments with this plant.

Soy Beans	Nitrogen %	Nitrogen content per plant (mgm.)	Number of nodules per plant
Without nodules	1·45	16·69	—
With ineffective nodules (Strain 507)	1·73	19·34	45

The presence of ineffective nodules did not reduce the nitrogen percentage of the plants, so that it seems unlikely that the root juice will have been seriously impoverished in this respect. The root juice in our experiments included nodule juice. Some nitrogen may therefore have been locked up in the cells of bacteria retained by the filter. A calculation was made of the total volume of infected nodule cells per plant inoculated with strain 507. This gave 71 mm^3. Allowing 20 per cent dry matter with 8 per cent nitrogen this would account for only about 1 mgm. of nitrogen, the loss of which could scarcely affect the nitrogen percentage of the juice. The removal of accessory growth substances by the bacteria is an unsupported possibility. It will not explain the fact that in our first experiment with soy beans (Table I, p. 481) juice from roots bearing ineffective nodules entirely prevented the growth of one strain of the Rhizobium. The production, in the infected root, of substances affecting bacterial growth explains this and also accounts for the observation that the bacteria in ineffective nodules multiply less and last for a shorter time than those in effective nodules. This poor growth occurs in spite of the fact that the nitrogen fixed per unit mass of bacterial tissue per day is the same for the ineffective strain 507 as for an effective strain[2].

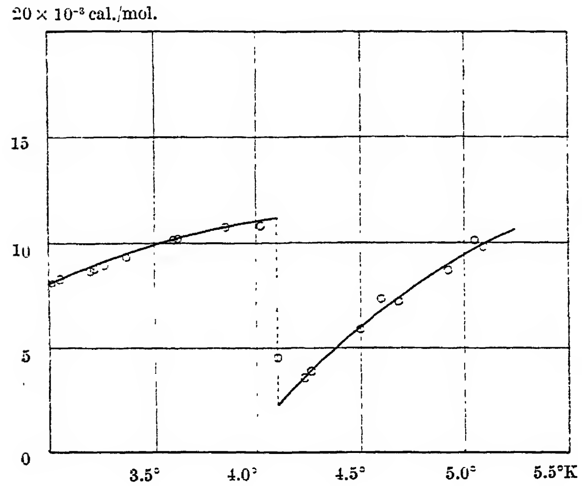
Specific Heat of Supra-Conductive Tantalum

THE behaviour of supra-conductive tantalum is far from clear. Early magnetic and electric experiments by Mendelssohn and Moore[1], and a more recent determination of the specific heat by Keesom and Désirant[2], indicated that pure tantalum showed properties very similar to a supra-conductive alloy[3]. Further magnetic experiments by Daunt and Mendelssohn[4] on a very pure sample, however, yielded results consistent with those obtained on other pure supra-conductors.

In order to clear up this discrepancy, it was decided to carry out measurements of the specific heat on very pure samples in the supra-conductive and in the normal state. These experiments were begun in 1939 by Dr. M. Désirant, of the University of Liège, and myself at this Laboratory, but had to be discontinued at the outbreak of war. By then all measurements in the supra-conductive state had been completed. As there is no prospect of resuming this research in the near future, we feel justified in publishing a short account of these results.

The experiments were carried out on five rods of very pure tantalum, kindly lent to us by Adam Hilger, Ltd. These rods were of the same batch (Lab. No. 10679) as the one used by Daunt and Mendelssohn. Their specific heat was determined in the temperature region between 3·5° and 5·5° K. The results are given in the accompanying graph.



As can be seen, the specific heat shows a discontinuity at 4·4° K., that is, exactly at the same temperature at which the electrical resistance disappears. This temperature is also the magnetic transition point determined by Daunt and Mendelssohn. The discontinuity amounts to about 9×10^{-3} cal./mol., which is in excellent agreement with the value ($9{\cdot}5 \times 10^{-3}$ cal./mol.) calculated by Daunt and Mendelssohn from magnetic determinations. From the drifts of the galvanometer attached to the resistance thermometer we could form an opinion as to the sharpness of the discontinuity, and conclude that the drop in the specific heat occurs in a very small temperature interval, not exceeding a few hundredths of a degree.

Our results disagree with those of Keesom and Désirant[2], who found a transition region 0·2° wide between 4·0° and 4·2° K. Their results agree, however, with the experiments by Mendelssohn and Moore[1] on slightly impure tantalum. It thus appears that, in sufficiently pure and homogeneous samples of tantalum, the changes of electrical resistance, magnetic induction and specific heat accompanying the establishment of the supra-conductive state occur at one and the same temperature. The outcome of the present research thus fully corroborates the conclusion reached by Daunt and Mendelssohn that pure tantalum shows the same behaviour as other pure supra-conductors and that the anomalous behaviour observed on some specimens is due to secondary causes.

In conclusion, we wish to thank Mr. A. Horseman for his help during the experiments.

"The Man of Science as Aristocrat"

IN NATURE of May 3 the Right Hon. J. T. C. Moore-Brabazon states: "The man who by his political efforts can get adequate milk to children deserves more of his fellow men than the inventor of the quantum theory; but in the narrow world of science, who gets the most attention and encouragement?"

This is to me the most encouraging statement I have read respecting a definition of science. Anyone who knows human nature and the great difficulties involved in the practical proposition referred to by Col. Moore-Brabazon will realize that the desired result can only be effected, and then with extreme difficulty, by applying the scientific method patiently to attain the desired end, and the man who does it may thank God for his success.

The quantum theory is a great achievement, but the supply of milk to children, and a host of similar problems, of vital importance to humanity, can only be obtained by intelligence of the first order directed to the special practical end and by the use of the methods of science.

The conception of science and the recognition of its achievements in such directions as that indicated should rank with the achievements in the relatively narrow world usually called pure science. As Prof. Wood Jones in a characteristic sally stated: "It takes more than a white coat and a test tube to make a man of science."

If the younger men of science with the requisite ability were encouraged to strike out in these difficult and unconventional directions, we should get a better world, and perhaps such a world might recognize their achievements; at all events I think so. But the most difficult and the greatest task of which I am aware is that of altering the outlook of men. Once that is done the practical consequences follow automatically.

"Crop Damage by Air Attack."

SIR JOHN RUSSELL in his article on "Crop Damage by Air Attack"[1] says: "The most serious risk is on the stubbles, if very dry weather should set in after the harvest." For the last nine years I have used a combine harvester, and have made a practice of burning some of the straw on the stubbles after harvest. In only two years have the stubbles been sufficiently dry to burn easily. Usually it has needed several men carrying burning straw about on pitch-forks to re-light the straw, which tends to burn for a short time and then go out. I have also used a tractor drawing a chain harrow with a mass of burning straw on it to keep the fire going. A combine leaves a longer stubble than a binder, and with the straw lying on top of this it should burn easily if any stubble will. My experience is that once straw and stubble have been well wetted by rain they very rarely dry out enough for the fire to take easily.

RESEARCH ITEMS

Effects of Insecticides on the Mid-gut Wall of a Larva

THE specific action of insecticides on the tissues of various insects is a little-explored field. Knowledge of this kind may prove of value in the selection, improvement and appliction of methods of insect control. A review of the physical and chemical effects of poisons on insect tissues cells and secretions is given by Trappmann (*Z. Pflanzenkrank.*, 48 ; 1938), while the most recent contribution to this subject is by P. A. Woke, of the U.S. Department of Agriculture. In the *Journal of Agricultural Research*, 61, 321–29 (1940), this writer discusses the effects of certain insecticides on the walls of the mid-intestine of the larva of the "southern armyworm" (*Prodenia eridania*). Lethal doses of the poisons were fed to the larvæ in turnip-leaf or sweet potato-leaf "sandwiches". The subjects of the trials were then killed and fixed after different intervals and the tissues examined histologically for comparison with control individuals. It appears that the action of arsenicals was followed by disintegration of the epithelial lining of the mid-intestine and damage to the visceral muscle-fibres. Ingestion of sodium fluoride resulted in disintegration of the substance of the cytoplasm and the nuclei. The epithelial cells of those larvæ that had ingested sodium fluoaluminate were greatly disintegrated and the cross-striations of the muscle-fibres were faint or obliterated. On the other hand, no changes in the epithelium or muscle-fibres followed the ingestion of barium fluosilicate, phenothiazine or rotenone that could be attributed with certainty to the substances named. Rotenone, it may be added, varies remarkably in its toxic action on different species of insects. Silkworm larvæ, for example, died within two hours from the effects of taking in minute quantities of this substance, whereas southern armyworm larvæ readily ingested 5–10 mgm. without showing ill effects. With regard to sodium fluoride, the observation of Hockenyos that this compound can be absorbed in lethal amounts directly through the integument of cockroaches, requires fuller exploration.

Termites and Soil Fertility

WHILE the destructive role of termites in the tropics is widely recognized, another aspect of their activities has so far attracted little attention, namely their effect on the physical and chemical properties of the soil, which they are known to influence to a great extent. Preliminary investigations carried out in Nigeria (*Nigerian Forester*, 1, 8 ; 1940) have shown that the soil of an active termite heap contained an increased amount of fine particles, which tended to improve the water-holding capacity of the soil. The carbon content of a heap was six times, nitrogen content about five times, phosphorus content two and a half times, and potash content more than three times that of the normal soil. Bearing in mind the wide spread of termites in Africa and the enormous extent of their underground activities, the problem deserves a very serious study from the points of view of termite bionomics, soils, natural vegetation, crops and forestry.

Collembolan Fauna of New Zealand

J. T. SALMON, entomologist at the Dominion Museum, Wellington, has recently given an important account of these insects (*Trans. and Proc. Roy. Soc. New Zealand*, 70 ; March, 1941). His memoir is the first attempt to discover and evaluate as nearly as possible the composition and distribution of the Collembolan fauna of the Dominion named. Some 101 new species are added to the New Zealand list which makes up the total number of species from that region to 185, exclusive of sub-species. The author finds that 77 per cent of the species are indigenous and explains this fact as being due to the long geological isolation of the country. The relationship of the New Zealand Collembola with those of South America is stated to be very weak as compared with its Australian affinities. In this connexion, however, it needs to be borne in mind that the Collembola of South America have, as yet, been very little studied. Summarizing, the author finds that the Collembolan fauna of New Zealand contains an ancient cosmopolitan element represented by such genera as Achorutes, Neanura and Onychiurus. An exceptionally strong affinity is betrayed with the Australian and Indo-Malayan forms. There is also a well-marked sub-antarctic element and a few, but important and striking, affinities with the American and African regions. It seems highly probable, according to the author, that the bulk of the species reached New Zealand by land bridges, from time to time connecting that country to northern Australia and the islands north of it, and extending towards Malaya. A comprehensive work of this kind will prove a stimulus to students for studying this group of insects and also for surveying the New Zealand forms still more thoroughly. A useful aid will be found in the diagnoses of the world's families, sub-families and tribes, while the 533 figures and the bibliography will prove an indispensable adjunct. The author mentions Stewart Island, the 'heel' of the South Island and the higher alpine regions over 4,000 ft. as being likely to contain many more species of these insects, adding that they were among the localities which he has, so far, been unable to visit.

Japanese Dinoflagellates

IN his work on the Peridinians of the Diplopsalis group, Tohru Hidémiti Abé describes many varieties of plate structure ("Studies on the Protozoan Fauna of Shimoda Bay. I.—The Diplopsalis Group", *Records of the Oceanographical Works in Japan*, 12, No. 2, March 1941). These may be regarded as some of the more primitive of the thecate forms leading up to the genus Peridinium. Both northern and southern forms are in the collection studied from Asamushi and Shimoda. Those from Asamushi are almost certainly partly southern but mostly northern, and those from Shimoda only southern. There is a very great variety of plate pattern among the members of this group which Schiller in Rabenhorst's "Kryptogamen-Flora" (1937) includes in the genus Glenodinium. A further work on the same subject by Abé ("Notes on the Protozoan Fauna of Mutsu

Bay. *Diplopsalis* and its Allies", *Sci. Rep. Tohoku Imp. Univ.*, Sendai, Japan, 1941), including the strictly systematic portion and literature, is in process of publication.

Wolf-dog Hybrids

WOLVES and dogs may be crossed to give fertile hybrids. N. A. Iljin (*J. Gen.*, **42**, 359–413; 1941) has studied the segregation of characters in *X* 101 progeny of a cross (made at the Moscow Zoo) between a zonar grey wild wolf and a black sheep dog. Mendelian segregation is demonstrated for hair colour and hair pattern, eye colour, ear form, size and skull characters. There is evidence of genotypical control of tail shape, nervous disposition, time of rut, and general appearance, but environmental influences play some part. The bark of a dog is purely a modificatory character and may be easily acquired by a wolf. The origin of the domestic dog from *C. lupus* is considered possible.

Differential Response to X-Rays of Diploid and Tetraploid Barley

A TETRAPLOID barley produced by temperature shocks on the diploid Opal *B* variety has rather a low fertility due in part to its autopolyploid state and to the consequent production of offspring with aberrant chromosome numbers. A. Müntzing (*Köngl. Fysiog. Galls.*, Lund F., **11**, 1–10; 1941) has X-rayed this barley to endeavour to create differences between the chromosomes and therefore increase the fertility. In the experiments he found that the response of tetraploids to X-rays was much less than diploids. For example, 85 per cent of the expected number of tetraploids produced seeds after a dose of 15,000 r., whereas only 38 per cent of the expected diploids produced seeds. The difference is attributed to the fact that a gene hit at one locus in a tetraploid is protected by three other genes on the homologous chromosomes as compared with one other gene in a diploid.

Genetics of Galeopsis

A. MÜNTZING (*Heriditas*, **27**, 193–201; 1941), continuing his experiments with Galeopsis has produced autotetraploid *G. pubescens* and *G. speciosus*, and diploid and tetraploid hybrids between these species. It is found that hybridization between the diploid species and between the tetraploid forms are fertile, while no crosses between diploid and tetraploid forms were successful. The author was able to cross tetraploid *G. pubescens* and tetraploid *G. speciosa* with *G. Tetrahit*, which is believed to be a natural polyploid derivative of *S. pubescens* × *S. speciosa*. The possibility of repeating the synthesis of *G. Tetrahit* is thus possible. Tetraploid derivatives of different diploid individuals of *S. pubescens* show differences in pollen fertility in the first tetraploid generation.

The Pacific Earthquake of November 10, 1938

THIS earthquake has been the subject of careful study by S. M. Mukherjee and M. R. Rangaswami (*Bull. Seis. Soc. Amer.*, **31**, No. 2, 121; April, 1941). The instrumental data used were the published readings of seismograms by the observers at the various seismograph stations together with the authors' interpretation of the original seismograms obtained at Bombay, Agra, Calcutta and Kodaikanal. Using the times of *P*, the epicentre was located at 55·3° N., 158·5° W., which is some eighty miles south of the Alaskan Peninsula in the Pacific Ocean. The earthquake occurred at 20h. 18m. 40s. G.M.T. The authors state that the analysis of the *P* and *S* residuals reveals three successive shocks, the second and third occurring 7 and 12 seconds after the first. Examination of the Indian seismograms points to a fourth shock, about 20 sec. after the first. The multiple character of the shock is brought out more conspicuously when the observed times are compared with Jeffreys' surface-focus tables and corrected for ellipticity, than when compared with normal tables. The epicentres of the first three shocks are found to be the same. Mukherjee and Rangaswami considered the identification of the second movement of *P* with *sP* and *pP* and that of *S* with *sS*, but this view was found to be untenable on account of the depth of focus and the character of the non-instrumental observations. The hypothesis of 'surface focus' (that is, less than 10 km. depth of focus) appeared to fit in best with the observations used. The magnitude of the shock was found to be equal to that of the catastrophic Bihar-Nepal earthquake of January 15, 1934.

Earthquakes and Crustal Structure (Southern Pacific Region, U.S.A.)

THIS was the subject of a paper by C. F. Richter of the California Institute of Technology, Pasadena, to the Sixth Pacific Science Congress ("Earthquake Epicentres and Structure of the Pacific Region of North America—Southern Part" by C. F. Richter, Proc. Sixth Pacific Science Congress; 1939). The data used were the epicentres of earthquakes during 1930–1933 determined by J. S. Hughes and Miss E. F. Bellamy at Oxford, together with epicentres since 1933 determined by the United States Coast and Geodetic Survey, and by the Jesuit Seismological Association at Saint Louis, U.S.A. For historical work recourse was also had to the catalogues of Townley and Allen, and also of Wood, Allen and Heck for the years 1769–1933. Epicentres determined at Pasadena were also used. From all these data a map was constructed showing by separate marking the epicentres of large normal earthquakes, minor earthquakes and the few of intermediate depth in the area. The most noteworthy feature of the map was the appearance of a nearly continuous belt of epicentres following the Pacific Coast from near Vancouver Island to Panama. The important structural loop through the West Indies was much less active than the Pacific Coast, so that these seismological data do not assist in the solution of the geological problems of the exact location and character of the loop. Since 1769 three major earthquakes have occurred in California: (1) January 9, 1857, centring near Tejon Pass, with large displacements along the San Andreas fault; (2) March 26, 1872, in the major Sierra fault zone at the edge of Owens Valley; and (3) the San Francisco earthquake of April 18, 1906, with displacements along the San Andreas fault. Allen suggested a division of the fault zone into segments where the rocks are strong and fracture only under great stress, occasioning major earthquakes, and segments where they are weaker, yielding more readily and occasioning less-violent shocks. This appears to be borne out by Richter's work, which shows that as regards numbers of shocks the San Andreas fault was surprisingly inactive, especially near the regions of the great earthquakes mentioned above and near to the earthquake stations at Pasadena, Mount Wilson and Riverside.

ACCELERATION OF THE RESPIRATION OF SURVIVING TISSUE

By DR. G. D. GREVILLE
RUNWELL HOSPITAL, WICKFORD, ESSEX

THE respiration of tumour tissue in a glucose medium is increased on addition of a suitable indicator (hereinafter called 'dye') or dinitro-*o*-cresol (DNOC), decreased by a narcotic such as phenylurethane. I observed in 1936* that when narcotic and dye are added simultaneously, the respiration is only slightly less than with dye alone. On the other hand, the narcotic almost abolishes the acceleration in respiration due to DNOC. The accompanying graphs depict an experiment with the mouse tumour *MC* 2146 in phosphate-glucose. Similar results were obtained with other concentrations of narcotic, DNOC and dye.

For some years it has been accepted that: (1) dyes 'by-pass' the oxidase-cytochrome system, acting as hydrogen-transfer catalysts, being reduced by activated metabolite through coenzyme and diaphorase, with subsequent autoxidation of the leuco-dye, and (2) narcotics inhibit the metabolite-activating dehydrogenases. These principles fail to explain[1] why concentrations of narcotic which strongly inhibit normal respiration (accompanying graphs) should at most but slightly reduce the oxygen-uptake in presence of dye. As (2) was apparently so well founded, there seemed difficulty in accepting (1) as the mode of action of dyes in surviving tissues. This difficulty has recently been removed by the observation of Michaelis and Quastel[2] that a narcotic at low concentrations, instead of inhibiting those dehydrogenases which activate glucose and its breakdown products, affects the respiratory chain at some link nearer the oxidase. Dyes 'by-pass' this link, and (1) can now be freely accepted as the mechanism whereby they increase tissue respiration. In the accompanying scheme arrows denote inhibition, and 'intermediate carriers' may include any or all of the following: coenzyme, C_4-acid catalysts, diaphorase, flavoproteins, succinoxidase factor, cytochromes.

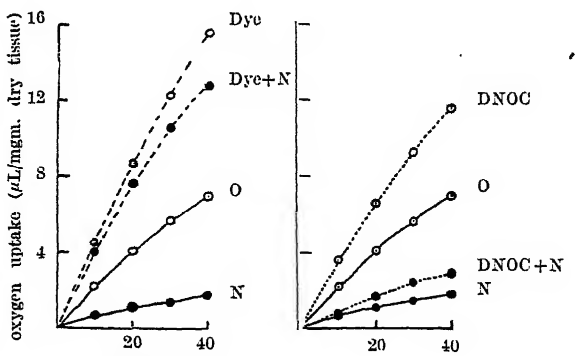
Narcotic Malonate - - - Cyanide

Metabolite | dehydrogenase | $\underbrace{\text{intermediate carriers | oxidase}}_{\text{Redox indicators}}$ | O_2

Gerard[3] suggests that in brain "the oxidase-cytochrome system does not limit the rate of oxidation, which depends on the dehydrases or their immediately related carriers". Since dyes accelerate brain tissue respiration[4], the latter is presumably either limited by the carriers nearer to oxidase, or else the 'master reaction' principle is inapplicable here, and the rate is limited by no particular link. In rat brain cortex slices, narcotic inhibition is apparently not overcome by dyes; but neither is cyanide inhibition. Indeed in cyanide-poisoned minced brain, hydrogen-transfer by cresyl blue is actually inhibited by glucose[5].

* While working in the Courtauld Institute, Middlesex Hospital, with the support of the Sir Halley Stewart Trust Fund and the International Cancer Research Foundation.

As seen above, DNOC will not restore the narcotic-inhibited respiration of tumour tissue. Several workers have noted that narcotics decrease the response of normal tissues to DNOC, and in the whole animal (cat), dial can prevent the increase in metabolic rate caused by dinitrophenol[6]. The difference in behaviour of dye and DNOC towards tumour tissue inhibited by narcotic is paralleled by their difference in behaviour when the inhibition is by cyanide[7], carbon monoxide[7] or malonate[8]. The graphs show that the link in the chain affected by narcotics cannot be stimulated or 'by-passed' by DNOC. Nitrophenols have only been shown to stimulate oxygen-uptake in intact respiratory systems. Their mode of action is still unknown. After kidney cortex slices have been subjected to anærobiosis, dyes have a reduced and DNOC an augmented effect on the respiration[1]. A speculative interpretation is that asphyxia damages the dehydrogenase end of the chain, and that this is the end stimulated by DNOC (cf.[9]). On the other hand, according to v. Euler[10] the concentrations of cytochrome oxidase and the cytochromes in tumours are strikingly low; since DNOC provokes a large respiration in tumour tissue it would have to provide hydrogen-transfer to oxygen by a cyanide-sensitive mechanism independent of oxidase-cytochrome. For this, however, there is no evidence.



O, NO ADDITION; N, NARCOTIC (PHENYLURETHANE) 0·003 M; DYE, BRILLIANT CRESYL BLUE 2×10^{-4} *M*; DNOC, DINITRO-*o*-CRESOL 10^{-5} *M*; DYE + N, DNOC + N, AGENTS ADDED SIMULTANEOUSLY IN ABOVE CONCENTRATIONS.

Difficult questions concerning C_4-acid catalysis and the path of carbohydrate oxidation in tumours, as well as the mode of action of substituted phenols, are raised by the effect of dyes and DNOC on tumour respiration inhibited by malonate. The typical experiment summarized below shows how, with glucose as metabolite, DNOC evokes a large malonate-sensitive respiration, the dye a large oxygen-uptake which is insensitive to malonate. The failure of DNOC to restore malonate-inhibited respiration is due solely to incompetence, for I have found that DNOC

in acceleratory concentrations does not inhibit the action of dye, when both are added together with malonate.

OXYGEN-UPTAKE (μL./MGM. DRY TISSUE/HR.) OF J.R.S. IN PHOSPHATE-GLUCOSE AT 38°

	No accelerator	DNOC 3×10^{-5} M.	Pyocyanine 10^{-5} M.
No malonate	11·4	23·1	26·5
Malonate 0.01 M.	8·9	9·2	23·8

The succinate–fumarate transformation must be involved in the respiration provoked in tumour tissue by DNOC, but not in the dye-catalysed respiration. Hence the route of carbohydrate oxidation in presence of dye, whether straight path or Krebs[11] cycle, cannot include the succinate–fumarate step. From its magnitude it is unlikely that the respiration in presence of malonate and dye represents a partial oxidation, and it is probable that the oxidations stimulated by dye and DNOC do not differ qualitatively. It would follow that the succinate–fumarate change involved in the DNOC-catalysed respiration is not in the path of carbohydrate breakdown, but is concerned with a catalysis of the Szent-Györgyi[12] type. Tumour tissue will not reduce oxaloacetate with any speed, either alone (Breusch[12]), or in the presence of glucose or glucose with DNOC[1]. Therefore, as Szent-Györgyi[12] has suggested, the catalysis is likely to be by the succinate–fumarate, and not by the malate–oxaloacetate, oscillation. Inhibition of the DNOC-catalysed respiration of *MC 2146* is overcome by high concentrations (0·06M.) of *l*-malate.

There is thus reason to suppose that, like narcotics, malonate inhibits hydrogen-transfer in a system in tumour tissue which is 'by-passed' by dyes but not by DNOC. As Szent-Györgyi[12] has found that in several dehydrogenations H passes to the acceptor dye through a C_4-acid system, the 'by-passing' observed in tumour tissue is not without interest.

ACTION OF THE EYES IN READING

BY using apparatus similar in principle to that of an electrocardiogram, M. Luckiesh and F. K. Moss, working at the Lighting Research Laboratory of the General Electric Company, Cleveland, Ohio, have investigated the action of the eyes in reading*. One electrode is placed in the centre of the forehead, and the other on one of the temples. The feeble electric currents produced by the eye muscles are amplified more than a million times, and recorded photographically by an oscillograph. The currents obtained are so weak, and the instrument is so sensitive that electrical disturbances are likely to arise from other biological processes taking place in the patient's body, as well as from electro-magnetic waves induced in his body by electrical apparatus such as lamps.

Reading ordinary type an average adult reader traverses a line of print $3\frac{1}{2}$ in. long in about six stages or fixations. Each shift from one fixation to the next occupies about 0·03 sec., and involves an electrical charge of the order of 0·00001 volts. One fixation comprises about nine letters. Fixations themselves vary in time from about 0·2 to 0·5 seconds. They tend to become longer towards the end of a line. If one fixation proves unsatisfactory, the succeeding one may shift backwards along the line, but it usually occupies a shorter period of time.

The remarkable control exercised by the perceptual faculties over the eye muscles is evidenced by the fact that an ordinary person reads about the same number of letters at each fixation, whether the print is in 4-, 10- or 18-point type. Between fixations visual patterns do not appear to be registered in the brain cortex, so avoiding blurring. The same is true of shifts in fixation from one line to the next, which may occupy 0·12 seconds, involving an electrical charge of 0·00006 volts.

* *School and Society*, **53**, No. 1376 (1941).

The fatigue of continuous reading may be appreciated from the fact that each fixation involves the simultaneous adjustment of six separate muscles to each eye, and that both eyes must work in harmony. Each set of type characters impress a new perceptual task upon the brain, giving rise to conceptual patterns as the letters read convey their message. Records of the electrical charges taking place in the eye muscles at the beginning and end of a long period of continuous reading are not dissimilar, indicating that the muscles retain the ability to respond adequately when perceptual faculties are beginning to show signs of fatigue.

Children often make twice or three times as many fixations as an adult in reading the same amount of print. This manifests itself in the slower rate of reading, as well as in the earlier stage at which fatigue sets in.

An average educated person when reading blinks about six times a minute. Each blink occupies about 0·3 seconds, and the electromyogram indicates that in blinking the eyes shut much more rapidly than they open again. During the process of blinking the eyes are rotated inwards and upwards, and then out again to produce an entirely new fixation. It used to be thought that blinking merely served to keep the cornea moist and wash away foreign particles. Now it is known that blinking also helps to relieve ocular fatigue.

Recent investigations have shown that the frequency of blinking is reduced if conditions for good vision are improved, as, for example, by better illumination, by means of glasses, and by using more legible print. During periods of increased concentration blinking may be postponed until a less critical stage is reached, but only at the cost of an earlier onset of fatigue.

SCIENTIFIC WORKERS AND THE CHEMICAL INDUSTRIES

DELEGATES from all parts of Great Britain (Scotland, Bristol, Birmingham, Billingham, London, Liverpool, Manchester, etc.) met at a chemical industries conference called by the Association of Scientific Workers on August 31 in Manchester to discuss the achievement of maximum technical effort behind war production and the problems of scientific staffs. This conference was the first of a series covering specific industries.

Speeches from the delegates showed the need and value of such conferences. Instances were cited of highly qualified scientific workers being engaged on non-essential work while production in other places was held up for lack of scientific personnel. Specific cases were given of lack of the systematic pooling of scientific information, leading to the holding up of production, and of the fullest use not being made of the resources of existing laboratories and equipment because of peace-time methods of organization.

The keynote of the conference was expressed by the chairman that only a greatly increased production could guarantee the support to the Allied forces which could defeat Fascism. It was generally agreed that the present hindrances to full utilization of all technical resources must be removed and all other questions, including the separate interests of both employers and staff, must be subordinate to this.

The following resolution was agreed upon unanimously:

"This conference of delegates from A.S.W. branches and groups in the chemical industries after discussion finds that the co-ordination and utilization of scientific and technical man-power is not commensurate with the effort needed in the present critical phase of the war. We, the delegates, pledge ourselves to initiate a campaign for maximum production. The organized activities of scientific and technical staff through the A.S.W. nationally and locally are necessary to implement this policy. We, therefore, propose the following programme: To ensure that

(1) The present position where all technical staff are not fully utilized on work essential to the war effort is quickly rectified; (2) real pooling of technical information and facilities takes place between Government departments and industry; (3) every incentive is given to increased effort on the part of technical staff by the removal of grievances attendant on non-payment for overtime and irregular salary increments and holidays; (4) women occupying technical and scientific posts in industry receive the same salaries and opportunities as men doing the same type of work; (5) adequate training facilities be provided for inexperienced personnel to rectify the effect of transfer and enlistment of technical staff; (6) the conditions of transference be safeguarded by consultation between representative organizations; (7) A.R.P. and safety organizations be under democratic control as envisaged by Government legislation.

To carry this programme into effect we propose the following action: (1) the calling of local works and laboratory meetings to apply the programme to local conditions; (2) initiation of approaches by the A.S.W. to all organizations concerned with production including managements of firms and national and regional production boards; (3) the closest co-operation with other trade unions; (4) strengthening of the A.S.W. as representing all technical and scientific staff."

FORTHCOMING EVENTS

Tuesday, September 16

THE FARMERS' CLUB (at the Royal Empire Society, Craven Street, London, W.C.2), at 3 p.m.—Mr. W. S. Mansfield: "The Maintenance of Land Fertility in War-Time".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TEACHER (MALE) OF CHEMISTRY AND PHYSICS in the Londonderry Municipal Technical College—The Director of Education, Education Office, 5 Guildhall Street, Londonderry (September 20).

ASSISTANT LECTURER IN SCIENCE, MATHEMATICS AND DRAWING in the Halesowen County Technical School—The Secretary, Halesowen Higher Education Committee, 21 Great Cornbow, Halesowen, Worcestershire (September 20).

REGISTRAR at the Huddersfield Technical College—The Director of Education, Education Offices, Peel Street, Huddersfield (September 30).

LECTURER IN NEUROPATHOLOGY AND NEUROPATHOLOGIST to Mental Hospitals of New South Wales—The Secretary, Universities Bureau of the British Empire, c/o University College, Gower Street, London, W.C.1.

LIVESTOCK OFFICER—The Secretary, Land Settlement Association, Ltd., 43 Cromwell Road, London, S.W.7.

COLONIAL DEVELOPMENT

WHATEVER form Anglo-American co-operation may ultimately take after the War, there are certain fields in which some continuity appears to be inevitable. Notably this is true of a whole range of questions such as the future of agriculture in the United States and in the British Empire, questions of nutrition and raw materials and colonial development. Moreover, measures already undertaken, such as the establishment of a joint Canadian-American Defence Board in 1940, the first of a series of moves towards closer collaboration between the United States and its northern neighbour, like the long-term leasing to the United States of British bases in the Caribbean Sea and on the Atlantic seaboard, can scarcely be dropped, much less reversed, on the termination of hostilities with Germany. They must affect British colonial and imperial policy as profoundly as they are modifying the isolationist attitude of the United States which has characterized the last twenty-five years.

This is indeed foreshadowed in the fourth and fifth points of the Atlantic Charter, as Mr. Churchill has aptly termed it. These points deal with the questions of access to raw materials, and collaboration in the economic field ; and they make it quite clear that Great Britain and the United States will not be parties to a world regime in which countries could be held to ransom through lack of natural products. The experience of the past twenty years has made it quite clear that policies of national self-sufficiency cannot meet the needs of humanity. Man is fundamentally a social animal ; and the progress of civilization—indeed its very existence—has come to depend on active collaboration not only between men as individuals but also between the nations. Such collaboration in the economic field is laid down in the Atlantic Charter as a principal factor in the new world order which must follow the defeat of Nazism. A nation can no longer be allowed to disregard the effect upon its neighbours of its policy in the economic and other fields.

The way in which Canada compromises the isolation policy of the United States has been indicated by Mr. John MacCormac in his recent book "Canada : America's Problem"*, in which he also emphasizes the significance of Canada in imperial affairs, and the shifting centre of gravity of the British Commonwealth. The whole tendency of present events is to accentuate the importance of Canada in the Empire, and whether or not the solution to the problems of Anglo-American relations lies in some form of English-speaking union as Mr. MacCormac suggests, his assertion that if Anglo-American relations are ever to be given an enduring basis, Canada must be their keystone, is not easily challenged. The foresight shown by Bismarck when he asserted that the

* Pp. 256 (London : Jonathan Cape, Ltd., 1941.) 10s. 6d. net.

inherited and permanent fact that North America speaks English is the greatest political fact of modern times is emphasized by all the rapid developments in Anglo-American relations of the past twelve months.

These new oceanic pre-occupations of the United States are creating new ties and a fuller community of outlook between them and the loosely knit oceanic structure of the British Commonwealth of Nations. The recent American occupation of Iceland is only one of a number of developments tending to bring the two democracies closer together in this way. Among these are the developments to which Lord Moyne referred in his statement in the House of Lords on July 9, regarding progress which has been made under the Colonial Development and Welfare Act. Already twenty-four schemes under that Act have been approved, the largest of which involves an expenditure of £200,000 for re-afforestation in Cyprus. Thirty-four more are under consideration, and at least seventy others are soon to be submitted. Full use is being made of expert help. The great majority of the new proposals are the result of the work of the Comptroller of Development and Welfare in the West Indies, Sir Frank Stockdale, formerly agricultural adviser to the Secretary of State for the Colonies, and a member of the Committee on Nutrition in the Colonial Empire.

Further evidence that careful plans are being laid for the development of the new constructive policy in colonial administration is seen in Lord Moyne's announcement of the establishment within the Colonial Office of a small official committee, with Lord Hailey as chairman, to prepare the ground for the decisions which would be needed to plan Colonial economics under the new conditions after the War, and to collect the facts that would help that Committee to deal with many other post-war problems that will arise. Since the great African Survey associated with his name, Lord Hailey has already carried out two other inquiries in connexion with African colonies of Great Britain and their relations with those of Belgium and Free France. His appointment to this new committee is clearly in line with ideas expressed last year at the Eighth American Science Congress on the fundamental conception of a world resources board and planning bureaux to promote the conservation and utilization of natural resources for the welfare of all nations in the interests of permanent peace.

The developments outlined by Lord Moyne and referred to again by him in the House of Lords on August 16, and the Colonial Development and Welfare Act are aimed at securing the economic and social development of the colonial territories. The new policy, with its recognition of the Colonies as societies, the welfare and development of which should be the guiding principles of their economic organization, and its determination to raise so far as possible the standard of living of all those classes whose standards are at present below an adequate minimum, however, also facilitates co-operation with other countries to that end. In many fields such as nutrition and health, including the attack on pests and diseases, like the rinderpest, the tsetse fly and the locust, to which Lord Hailey referred, and also in the development of an economy of mixed farming and native industry or of a constructive system of social services, we have much to gain by pooling experience and knowledge with our Allies and partners.

The foundations for such scientific co-operation already exist, and Lord Moyne's statement should give further inspiration to workers in such fields. There are, however, even more powerful factors implementing such co-operation. The prosperity and future of the Colonies must be profoundly affected by the changes brought about by the War. Quota schemes for imports from various countries, and commodity schemes which ensure various producing countries a fair share of the world market, are rapidly superseding older systems of tariffs as a means of controlling the direction of trade. Government control would involve much more than the readjustment of surpluses, and the organization of export marketing already achieved with the Colonies of our Allies must be continued in some shape. This involves a co-ordinating authority on a world-wide, a regional, or a continental basis, and the new policy accordingly seems likely in practice to involve increased international co-operation, while its spirit assists such relations.

American opinion is clearly coming to face the possibilities of framing programmes relating to colonial areas, raw materials, shipping, migration and other questions so as to remove obstacles to the full use of the world's resources, as the *Fortune* round-table discussion showed. The handling of colonial problems in the spirit of wise and far-sighted generosity which informed Lord Moyne's statement cannot fail to invoke Anglo-American co-operation in this and in other fields. The crop purchase schemes and the much larger schemes under the agreements recently made with Australia and New Zealand for dealing with the surplus produce of the two Dominions during the War, and which are to be extended to South Africa and the Colonies, are not merely designed to prevent the worst forms of distress and keep the colonial producers going. The agreements are indeed an economic necessity to the Dominions if they are to make their contribution to the War and to maintain a healthy economic life, but at the same time

they are part of a great scheme of international reconstruction.

The building up of reserve stocks of food contemplated in the agreement is concerned not only with the possibility of a long war but also with the difficult food situation that must arise when the War ends. The agreement ensures that large reserves will be available when the War ends, and these reserves will be used, in part, according to the promise of the British Government, to relieve the needs of the occupied countries of Europe. Canada stands by these arrangements because her staple food product is wheat, which will be handled at an early meeting of the International Wheat Committee in Canada. The policy, however, will be extended to Canada and by that time, as a result of the work of the Willingdon Commission, some of the South American States may also come in. Moreover, the present agreement already involves co-operation with the United States, for example, in the supply of tin-plate for meat canning, of milk-drying plant to New Zealand, while it is expected that the United States will take some of Australia and New Zealand's surplus meat as shipping is available, sending Great Britain an equivalent amount over the shorter Atlantic route. Negotiations are also proceeding with the United States for the release of refrigerator ships to be used in carrying the surplus food stocks, and other work in this field is being carried out by the Leith-Ross Committee in regard to co-ordination of storage arrangements.

We have here the beginnings of an important policy for international co-operation in handling food stocks and primary products. It needs little imagination to see how with wise handling it could develop into a far-reaching attempt to raise standards of living in backward areas all over the world, and to translate minimum standards into ideal standards on a firm basis of scientific and social research. Vision and foresight will of course be required to see that developments out of these agreements continue to facilitate common action with the United States and the Latin American republics, and do not involve Great Britain in any exclusive imperial block. The moral obligations of economic leadership must be acknowledged by Britain and the United States, if only to enable them to solve their own problems of surplus food production and economic freedom. The major responsibility may indeed well rest with the United States, but the constructive international statesmanship required is not the affair of any one nation alone.

The prospects thus opening up before us are far from being limited to the simultaneous résumé of the primary producers and the starved populations of the world. The relief of hunger is coupled with the struggle against disease, the elimination of malnutrition and the application of the knowledge of nutrition to the building of a sounder social and economic order, the reorganization of transport and the return to civil life. Here, as Mr. Winant has recently reminded us, the International Labour Organisation is still making important contributions, and a firm basis already exists for that international co-operation which is imperative if we are to deal effectively with these problems. Out of that practical co-operation may well develop by degrees the framework of organization essential in a stable world order.

The primary importance of Anglo-American co-operation and leadership should not lead us to overlook the fact that co-operation of all the free peoples is required to build a new order in which the four freedoms for which we contend are firmly enshrined. It is doubtful whether we have even yet begun to utilize to the full the opportunities for mutual understanding and for co-operation in the essential research for the organization of a new order which are inherent in the presence in Great Britain of Governments representing so many of the submerged States of Europe. One suggestion which has been advanced is the establishment in London of a social research centre on the model of the Institut Solvay in Brussels, where officials of these Governments would meet to discuss their social problems. Equipped with a library and a staff able to give expert advice in the choice of books and on sources, such a centre might do much to promote the sympathetic understanding of our respective social systems, and to stimulate investigations and co-operation which would bear fruit in the work of the International Labour Organisation.

The suggestion is one that merits serious exploration, for it could undoubtedly clear away many misunderstandings and differences. Less spectacular than the Inter-Allied meeting at St. James's Palace on June 12, it could make an important contribution to unity and to the task of world reconstruction, if not indeed to the implementing of the war effort. The opportunities and possibilities which are already to our hands through the changes brought about by the War are already so great that only the grossest bungling can fail to use them as stepping-stones to an order worthy of the sacrifices now being made in defence of freedom Nowhere is this truer than in imperial and colonial affairs, where we can attest the sincerity of our ideals and of our conception of trusteeship. There we can explore the possibilities of co-operation with the United States and the other free nations to establish economic freedom in a new way and to eliminate some of the underlying causes of war ; there, too, perhaps we may gain the experience out of which a new and adequate form of world order may emerge.

UNIVERSITY OF MICHIGAN EXPEDITIONS TO WEST GREENLAND

Reports of the Greenland Expeditions of the University of Michigan

Part II : Meteorology, Physiography, and Botany. William Herbert Hobbs, Editor. (University of Michigan Studies, Scientific Series, Vol. 6.) Pp. vii+288+47 plates. (Ann Arbor, Mich. : University of Michigan Press ; London : Oxford University Press, 1941.) 5 dollars.

THE more general reports upon the series of five expeditions to West Greenland undertaken by the University of Michigan between the summers of 1926 and 1933 are published in this volume. (Part I, which appeared in 1931, was limited to "Aërology, Expeditions of 1926 and 1927–29"; the originally planned third and fourth parts will not be published.) The present part is predominantly meteorological, but the five papers which comprise it cover such a wide range of subjects that they seem best considered separately; nor are they of similar value, or necessarily concerned with the same geographical region.

(1) *Meteorological Studies*, by J. E. Church. The first part of this paper deals with "Climate and Evaporation in Alpine and Arctic Zones", the alpine zone being the Lake Tahoe Basin lying around lat. 39° N. and long. 120° W. in the central Sierra Nevada and the arctic one being the Holstensborg region near the arctic circle on the west coast of Greenland. Useful tables indicate the rates of evaporation of water, snow and ice under different conditions; under comparable conditions in both regions these tend to be in the ratios 3, 2 and 1, though around melting-point the results are very variable and the last two figures may actually be reversed. Wind and temperature are the dominant factors in determining the rate of evaporation, which during the incidence of *foehns* may be extraordinarily rapid.

Progressing inland in the Holstensborg region the climate tends on the whole to become more continental in type, although (as in other northern regions) unusually favourable conditions are to be expected locally around the heads of the longer fjords, while on the inland ice the relative humidity is consistently greater and the temperature range sometimes lower than near the coast. Plant ecologists will note with interest that at one point well away from the coast, evaporation during the warmest two months of summer scarcely exceeded the rather low precipitation (including condensation), so that "the winter accumulation of moisture still remained in the humus and underlying blue clay as a source of growth". The protection of the soil by a "thick mat of tundra" reduced evaporation ("including that amount transpired by the tundra") to 63·1 per cent of what it was from open water, which "shows vividly the xerophilous . . . character of the Arctic tundra".

The second part of the paper deals with "Temperatures of Arctic Soil and Water", the studies indicating that inland in West Greenland "the soil rather than the icecap is the cause of the low water temperatures which prevail, aided somewhat by supercooling at night", for "frost . . . exists even at the end of the season at the depth of 16 to 23 inches beneath the surface". Seawater temperatures are variable locally, depending on currents (themselves affected by winds), proximity to the shore and to icebergs, etc., as well as on the season; on the whole they are little lower in north-central than in south-central West Greenland.

(2) *Report of the Northern Division of the Fourth . . . Expedition*, 1930–31, by William S. Carlson. This paper is again in two parts, the first of which describes detailed aerological and meteorological studies made near the inland ice east of Upernivik (lat. 72° 47′ N.). Numerous pilot balloon flights showed that the mean monthly velocity of free-air wind increased steadily with altitude from 250 to 2,000 metres, this increase on the average totalling more than 100 per cent. At higher altitudes there were further, but less regular, increases until 8,000 m. was reached, and then a marked tendency to decrease around 10,000 m. Calms were very few above 250 m. and none was observed above 2,500 m. Wind direction also changes chiefly in the first 2,000 m. Detailed studies of four storms when correlated with published observations made synchronously in other parts of Greenland, at sea and abroad, bring to light remarkable local variations but further confirm the general belief that the 1,600-mile-long ice-cap of Greenland "exercises a dominant control in the weather of at least a part of the Northern Hemisphere", for "it impedes the natural progress of some storms, redevelops energy in others and is responsible for their inception".

The second part of the paper is on the geology and glaciology of Upernivik Fjord and the region northwards to Inugsulik Bay. It is based largely on observations made during travelling under winter conditions and is accordingly rather sketchy. It appears, however, that the fronts of some of the glaciers in this region have receded as much as 2,000 or even 5,000 ft. since the visit of Ryder in 1886–87, and that in this interval fresh nunataks have emerged. The large glaciers which come from the ice-cap, dissecting the ice-free coastal strip and calving actively into the sea, show the greatest rate

of flow around their centres, the velocity decreasing towards the sides. On the Upernivik glacier the much greater maximum velocity (67·44 ft. in twenty-four hours) observed in April 1931 than in April 1887 suggests that Ryder's claim in excess of 100 ft. in twenty-four hours might be exceeded during summer on this glacier nowadays, as the summer rate is liable to be considerably greater than the spring one.

(3) *Meteorological Report of the University of Michigan – Pan American Airways Greenland Expedition, August* 1, 1932–*July* 31, 1933, by R. L. Belknap. This was the fifth and last expedition of the series and also functioned as one of many units making investigations during the "Second International Polar Year". It was based on Nugssuak Peninsula, in the northern part of the region described in the last paper. The lowness of the average daily air temperature (less than 10° C. in all months) was attributed to the modifying effect of the inland ice near which the station was situated, although very rapid changes in temperature and pressure occurred especially in relation to storms when the wind sometimes exceeded 100 m.p.h. The results of previous expeditions were confirmed by the observations that "the southeast winds were the most frequent and were of the highest velocity", and that although storm effects were often remarkably local the major disturbances were in Greenland first observed in the extreme south, whence they apparently "traveled up the coast on both sides" without crossing the ice-cap.

(4) *Physiographic Studies in the Holstensborg District of Southern Greenland*, by R. L. Belknap. In this region, which is unusually dry, the ice-free marginal land is wider than elsewhere in West Greenland, being up to 110 miles in width although still dissected by fjords and valleys. The outer coast is rugged and mountainous but the country inland, which is uninhabited and less known, is of rounded hills and numerous lakes of all sizes. The topography appears to support the theory of fjord origin by glacial erosion guided by joint systems rather than by the enlargement of fractures chiefly by stream action. Shells of recent marine animals found on terraces more than 100 ft. above sea-level indicate a corresponding rise from the sea in relatively recent times. Previously this district, like other parts of Greenland, had been one of great submergence ; now there are some suggestions of slight submergence again. It is reported as "evident that the entire area as far as the present coast line has been covered by the icecap". Wind is an important agent of erosion and deposition ; it may considerably affect the shape of a boulder (rock not specified) in a single year. The importance of solifluxion is also noted but the "explanation of the formation of soil and rock polygons" was surely not "worked out" satisfactorily by the few authors cited.

(5) *The Vascular Plants of an Inland Region within the Holstensborg District of West Greenland*, by Carl O. Erlanson. This last and shortest paper is most disappointing. The area concerned is a limited one at the head of Söndre Strömjord, occupied chiefly by low, rounded hills of gneiss interspersed with small lakes. But the ecological notes on "Vegetational Aspects" are scrappy and studded with doubtful statements and unwise generalizations, while the "Systematic List" which comprises most of the paper contains many inaccuracies. We are even told on p. 265 of *Cassiope tetragona* that it "may become a dominant plant over large areas, sometimes to the entire exclusion of other species except mosses and liverworts" and on p. 273 that it is "Rare. A bog plant" (which it is not characteristically in any of a dozen arctic and subarctic regions known to the reviewer). There are other instances in which the citation of the habitat of a single gathering of a species in the systematic list is misleading, while a glance at any part of the paper will show that the nomenclature is badly out of date. A footnote informs us that this contribution was "prepared and submitted for publication in the spring of 1929". Since then arctic botany has advanced so enormously that a large proportion of the names used in this paper are wrong or doubtful and most of the records claimed as particularly significant are no longer so, if indeed they ever were. The result is a plethora of inaccuracies the majority of which would have been questioned by a competent plant taxonomist or phytogeographer.

One lays down the volume with rather mixed feelings. Obviously much useful fact is recorded in it, often for the first time ; obviously, again, the editing leaves much to be desired. The numerous photographs are usually good but their subject is not always significant. There are more than the apparently inescapable minimum of omissions and inaccuracies, as well as inconsistencies and unwarranted generalizations, while whole "lines" of literature were persistently neglected by the authors, including much that has been written about the Canadian side of Davis Strait and Baffin Bay. Had the investigators realized that central West Greenland is only a small part of the great arctic checkboard, many of their conclusions would have been less sweeping. The impression, then, is one of youthful enthusiasm rather than mature scholarship ; nor do the total results compare favourably with those obtained by some other recent northern expeditions which had much more limited resources in time, personnel and particularly money. NICHOLAS POLUNIN.

A NEW DEAL IN EDUCATION

Education for the People
By Dr. F. H. Spencer. Pp. vii+306. (London: George Routledge and Sons, Ltd., 1941.) 7s. 6d. net.

TOTAL war is accustoming us to the necessity for radical changes in the pattern of our society. After the War we shall not be able to go back to our old way of living. We may try to reinstate the old order, leaving it to the inevitable next cataclysm to teach us what the present one fails to do, or we can go forward with imagination and resolution to create a new order. The first few years after the War will be crucial. Will the resolution we are showing now be spent, or baffled, as it was after the War of 1914–18, or will it carry us on to the creation of a new pattern of living in which war will not be inevitable? The decision depends a good deal on people thinking now what we shall have to do. Some people are thinking now, and though we are not yet within sight of winning the War, it is not premature to be doing so. In the field of education, the officers of the Board of Education have their plan of reconstruction, but for not very convincing reasons it remains a secret plan. Dr. Spencer does a public service by making public now his plan for a 'new deal' in education.

It is symptomatic of the attitude of our people to education that the developments Dr. Spencer demands are so far-reaching that, if the experience of the years after the last War is a guide, we shall have to struggle very hard to secure them, and yet at the same time they are not nearly radical enough to meet the situation. Dr. Spencer's proposals are not revolutionary. He advocates courses of action which the better local education authorities, the teachers and others have been urging for years. We must, of course, see that nursery schools are available for all children of nursery age and not merely for a few thousands of them, and that enough teachers are trained to staff the schools. The size of classes must, of course, be reduced from forty or fifty and more to thirty or less. The Hadow reorganization, still left half done after fifteen years, must be rapidly completed. School buildings, eighty per cent of which Dr. Spencer asserts to be out of date, must everywhere be brought up to the more generous and efficient standards of our best examples. The school-leaving age must be raised—Dr. Spencer says to fifteen—and adolescents must make the transition to full-time employment through a period of half-time attendance at day continuation schools up to the age of eighteen. Every boy and girl whose potentialities can best be realized by education of the secondary school kind must be enabled to go to a secondary school without fee. Children must have the safeguard of a medical examination, not at intervals of several years but annually; the insurance companies know the advantages of this, the Board of Education, too, must see them.

These proposals are literally modest ones in relation to the reasonable needs of our children and our country. The case for them, argued so convincingly by Dr. Spencer, may be regarded as established, and their fulfilment is now urgent. In war-time we are carrying out far bigger schemes with far more urgency, and at a far greater cost than anything Dr. Spencer requires. To meet our immediate educational needs, Dr. Spencer requires mainly capital expenditure of £100,000,000 on new buildings in the next five or ten years, and a doubling of our present small annual expenditure on the maintenance of education to £100,000,000. He requires further that the President of the Board of Education should be "a first-rate statesman of real eminence and power". (The publication of Dr. Spencer's book, by the way, has not been speedy enough to keep pace with the changes in the presidency, and the "administrative grandfather" of his president is already a great-grandfather.) Other requirements are a real Board of Education with 'guts' and an active and informed local electorate.

It is a paradox that to many a man in the street this new order will seem visionary and impracticable, while to many who believe they discern the causes of our present discontents it will not seem a new order at all. The ignorant and the faint-hearted will consider education lucky if it gets so much: those who know that our society cannot merely be patched up will want to shape the things to come more boldly and more creatively than Dr. Spencer. They will, for example, think him somewhat timid in not raising the school-leaving age to sixteen for the boy of average ability, as it already is for his more intelligent fellows in the secondary school and his less intelligent ones in the special school. They will be unimpressed by the demand for juvenile labour, and will not consider the time necessary for the more intelligent to reach the modest standard of the School Certificate too long to prepare the less intelligent for the difficult and responsible business of living in a world of great social and economic as well as scientific complexity.

Dr. Spencer insists, and all students of education

and of society will agree that he rightly insists, that an educational system always shares the characteristics of the social system of which it forms part. He insists, and all democrats will agree that he rightly insists, on equality of opportunity in education. He does not make it clear that he sees there can be no equality of opportunity in education unless there is at least a much closer approximation than at present to equality of opportunity for the enjoyment of the goods of life which our society renders possible. The opportunity in which Dr. Spencer demands equality is the opportunity to be trained to take part in a highly competitive struggle which results in very unequal opportunities for security and the enjoyment of what life can offer. As long as the arena is open, the junior and even the infant schools will train their children for the scholarship examination, the secondary school will train its pupils for the privileged position which the School Certificate confers. The senior school may achieve parity of status with the secondary school, in the size of classes and the qualifications of teachers; but parents are not much interested in the size of classes or the qualifications of teachers; they send their children to the secondary school, if they can, because they know that that way lies a more secure, a better-paid and more socially esteemed kind of job. The implications of Dr. Spencer's two propositions, indeed, go deep. If we follow them without flinching we shall find that in our new deal we shall have to reshuffle the hands more thoroughly than Dr. Spencer suggests.

R. A. C. Oliver.

TENDENCIES IN BIOCHEMISTRY

Annual Review of Biochemistry
James Murray Luck, Editor; James H. C. Smith, Associate Editor. Vol. 10. Pp. xi+692. (Stanford University P.O., Calif.: Annual Reviews, Inc., 1941.) 5 dollars.

It has become increasingly difficult to escape from the War. Our daily life, our friends, the newspapers are full of it; it pops up in any book we get from the library, and our last random selection from our own shelves was the Trojan war on which, according to gossip, much of our strategy is still based.

The "Annual Review of Biochemistry" brought us a breath of fresh air from California. We were able to picture the Stanford University in its jewelled setting as we saw it, not bombed and in ruins in defence of freedom of thought and action. Even so, the editors complain of delays and irregularities and contributors are less international.

This is the tenth year of this valuable volume, and we have grown to wonder how we ever got on without it; perhaps because the output of papers was much smaller. Apparently nothing can now stop the publication of individual experiments as scientific papers, and the old-fashioned complete paper is a thing of the past. No one can keep up with the literature as a whole; someone has to write summary articles in each particular field; someone else has to write a section in an annual report. In these some degree of criticism and selection is exerted, whereas in the large dictionary-like compilations the editor puts in all he can find and leaves the reader to take his choice and select the grist from the chaff.

Before long it may be impossible to publish an abstract of every paper both on the ground of cost and unwieldiness. But nothing will stop the writer of scientific papers.

There is progress on every front in biochemistry. It is akin to the discovery of a new continent fertile with running streams: the covered wagons of investigation are well equipped. Progress is largely in detail, the great truths will emerge later when the ground is cleared. For example, a great deal has become known about biological oxidations and reductions, a subject which would be easier to understand if its followers wrote in English instead of shorthand. This, alas! must be a universal criticism.

More enzymes have been purified, but there has been little real progress. A lot more is known about the polysaccharides and, as was to be expected, now that a definite search is being made for these a very considerable number has been discovered. In a year or so it will be possible to say whether Nature, besides its main products of cellulose and starch, joins up the odds and ends as she listeth, or whether any definite relationship, as the polymerized molecule grows larger and larger, is to be observed. Much interest is attached to alginic acid, the polyuronide from common seaweed, which is likely to be of very considerable industrial importance, and may be eventually made on a large scale. The presence of the acid groups in the molecule gives the chance to make a range of salts of varied properties.

It is being realized that we do not know nearly enough on the chemical side of the amino acids and of the constituents of proteins. Such work is

laborious, and has been out of fashion, but it is being taken up again. Real progress is being made with the study of phosphorylase, the enzyme responsible for the reversible conversion of glycogen or starch into glucose. The reviews make little mention of the synthesis of starch from glucose phosphate in this way achieved by Hanes at Cambridge: it is the most outstanding piece of work of the last year or so.

Hormones and vitamins still cause the publication of thousands of papers: it is to be doubted whether Lord Woolton reads any of them. Here and there is progress, also much doubtful work; it will require another ten years work to see the plain where the trees once stood in this subject; the reports give them 150 pages.

Nutrition is the subject of greatest importance to-day and to-morrow, and there is just a chance that something of real value to the peoples of the world may come out of the work. There are good reviews on nutrition of man, animals and plants, including the burning questions of soil deficiencies and minerals. These are highly controversial questions, and the practical farmer does not always accept the conclusion of the scientific worker. If only the excreta of the petrol engine were of value to the land all would be well—otherwise, according to some, we must be prepared to return sewage to the land or find out how to make humus on the largest scale. There is need for many years of experiment and for critical examination of the results, but the subject is so important that both zealous workers and the necessary ample funds are likely to be available in many countries.

We have a final plea to the editors, namely, that the writers of each section of the report should preface it by a paragraph or two indicating the chief achievements and tendencies in the subject Apart from easing the task of the reviewer, such would appeal to almost every reader of the sections in which he is not an active worker.

E. F. ARMSTRONG.

DEFICIENCY SYMPTOMS IN PLANTS

Hunger Signs in Crops

A Symposium prepared by George M. Bahrt, Bailey E. Brown, Arthur F. Camp, H. D. Chapman, H. P. Cooper, O. W. Davidson, Ernest E. De Turk, George N. Hoffer, Henry A. Jones, James E. McMurtrey, Jr., Edwin R. Parker, Robert M. Salter, George D. Scarseth, Joshua J. Skinner. Edited by Gove Hambidge. Pp. xii+327+79 plates. (Washington, D.C.: National Fertilizer Association, Inc., 1941.) 2.50 dollars.

UNHEALTHY growth of crop plants, apart from trouble induced by diseases or pests, is usually associated with physiological causes, which in some cases imply excess or deficiency of various substances utilized in the metabolism of the plant. The relative quantity of these substances is immaterial, as the plant suffers as much from a deficiency of an element such as boron, of which only a minute trace is required, as from a deficiency of a major element, such as nitrogen, required in large quantities. In practice it is deficiency rather than excess that is most likely to occur, and various signs and symptoms present themselves.

Only by careful and accurate observation and experiment is it possible to ascertain the meaning of these symptoms, and considerable experience with any one crop is needed before the observations can be systematized and set out for the guidance of the ordinary grower. Work on deficiency symptoms or "hunger signs" has been carried out by a large body of scattered observers on a considerable variety of crops. In the volume under review investigators with special knowledge of certain crops or groups of crops have epitomized the present state of our knowledge of the known deficiencies for those particular plants. Major and minor nutrients are all considered, and the symptoms, cause and ameliorating treatment are discussed.

The range of crops covers tobacco, cereals, potato, cotton, vegetables, deciduous fruits, legumes and citrus, thus giving a comprehensive survey of the position with regard to the chief world crops. Many illustrations are given in black and white and in colour. As is usual with colour photographs these need careful interpretation, for it is easy for a non-expert to be misled into attributing hunger signs to the wrong element, especially if a bias exists in favour of any particular nutrient. If this is borne in mind the illustrations provide an extremely useful guide and fill a want that has long been felt by workers in this field. A key to the plant nutrient deficiencies is given for most of the crops, which provides an excellent supplement to the illustrations. The citation of references is wisely restricted to a small number specifically associated with each crop.

Altogether, the committee on fertilizers of the American Society of Agronomy is to be congratulated on the production of a volume which will prove specially useful as a laboratory guide for all workers on plant deficiencies, as well as an illuminating text-book for growers and for students of plant life.

W. E. BRENCHLEY.

SCIENCE AND WORLD ORDER

By SIR RICHARD GREGORY, BART., F.R.S.

AT the Cambridge meeting of the British Association three years ago, a new Division for the Social and International Relations of Science was constituted. Since then the full forces and resources of science have been used to devastate the civilized world. Responsibility for the discovery of these powers of destruction must be accepted by men of science, but communities and Governments decide how they shall be used in purpose and policy. No limit can be seen to such powers, and no end to the horrors they present to human life, when exercised without regard for its sanctity.

Whether scientific knowledge is used for social betterment or to make civilization a mockery depends upon statesmen and not upon men of science, who, however, alone understand its possibilities. It may not be necessary to have intimate acquaintance with such knowledge in order to anticipate effects of its applications, but it is obviously desirable for statesmen and administrators to have full appreciation of its powers. Without such understanding and insight, no social structure can be made secure against disruption.

The Conference on Science and World Order, to be held at the Royal Institution, on September 26–28, will deal with a few relations of science to government, administration and other agencies concerned with constructive planning for the present and the future (see NATURE, September 13, p. 311 and p. 338 of this issue). In the main, the point of view will be that of world resources and human needs generally, and not those defined by geographical or political boundaries. Distinguished ambassadors and other leaders in close contact with governmental authority will participate in the conference, either as chairmen or contributors of papers. It is believed that the conference will thus promote social and international contacts of far-reaching consequence.

Science is responsible for the discoveries of these powers, and engineering for their applications. Knowledge of this kind, referred to use or action, determines the material shape of civilization. It is available to the whole world for work and thought; either to increase the amenities of human life everywhere or to bring misery and violent death to the peoples of the earth. We see to-day the devastating effects which scientific discovery and invention can have upon civilized life when their might is made the sole arbiter of right. The acceptance of this claim means the rejection of all ideals of human fellowship, and reversion to conditions of the jungle.

Schemes of social reconstruction naturally differ for different places and peoples: but they should all be capable of fitting into a world framework. This means planning in an international instead of a national spirit, while giving every nation or community full opportunities to develop in its own way, provided that the common end is the betterment of conditions of life.

When civilized peoples agree to unite in such a commonwealth in which each group is autonomous, without conflict of general purpose, we may hope that the world will be saved from the dangers which now threaten to destroy it. Man has shown himself capable of rising above his animal instincts by his activities in many directions, and, wisely guided, he can use the gifts of scientific knowledge as agencies of good instead of instruments of evil.

In the terrible conflict in which many nations of the world are now engaged, there can be no doubt as to the side upon which the true spirit of science is fighting. Men of science would be false to their traditions if they failed to defend their pursuit of knowledge from the forces which now assail it. They are united with all free citizens of the world concerned with progressive human development in resisting such attacks and eliminating the evil influences which make their achievements diabolic instead of divine.

The commonwealth of science is a true democracy, in which no distinctions of birth, race, or geographical boundaries are recognized. It cannot tolerate the use of force to exclude members of any communities from belonging to its fellowship, or to deprive any citizens of their fundamental human rights. The democratic principles of science are much the same as the scientific principles of democracy, and free men of science everywhere can subscribe to them.

A declaration of these principles will be made at the close of the conference. It accepts for science the world outlook embodied in the declaration of the rights of man of the Sankey Committee, advocated by Mr. H. G. Wells, and its spirit is the same as that of the momentous Anglo-American statement of peace aims, though it does not pretend to be of the same significance. The cause in which all such declarations are made is that of all humanity. It is the cause of progressive civilization and can be attained only by action in which wisdom is combined with knowledge.

PARACELSUS (1493-1541)

By Prof. J. R. Partington, M.B.E.

PHILLIPUS THEOPHRASTUS BOMBASTUS VON HOHENHEIM, who afterwards assumed the name Paracelsus to indicate that he believed himself as great a physician as Celsus, was born towards the end of 1493 at Einsiedeln in Switzerland, then part of Germany. His father was a practising physician of repute and his teaching laid the foundation of the medical career of the son. Of the early life of Paracelsus nothing is known beyond conjecture until 1526, when he appeared at Strasburg as a physician, described as doctor and admitted to citizen rights and to a Guild of Surgeons. He studied medicine, but it is not known how. In his writings he emphasizes that he got most of his useful knowledge from artisans and from the humbler assistants of the medical profession, whom he rates higher than the schools. On the other hand, he also once stated on oath that he had become a doctor of the University of Ferrara, and it is difficult to understand his short-lived official appointments unless he was properly qualified. Besides his medical knowledge, Paracelsus also says he had great experience for a long time with many alchemists and metallurgists, and he undoubtedly visited many mines and smelteries in his travels some time about 1514. These travels probably took in most European countries, including England, at various times, but those further afield are doubtful.

The information Paracelsus acquired from the miners and alchemists seems, from what he says of it, to have been fairly superficial and such as could have been picked up by almost anyone in conversation. It would, however, have suggested to him the possibility of using metallic preparations as remedies. If he did study in Italy this would have provided a direct source for some features of his teachings, since his so-called philosophy is a mixture of German folk-superstition with the thaumaturgic elements of Neo-Platonism, then popular in Italy by reason of its revival by Ficino. The view that Paracelsus himself was the originator of the use of chemical remedies is quite mistaken, since this had been gaining ground since the time of Arnald of Villanova, who died nearly two centuries before Paracelsus was born.

While at Strasburg Paracelsus must have enjoyed more than a local reputation as a physician, since he was sent for by Frobenius, the celebrated publisher of Basle, whose illness had resisted the attempts of the physicians of that town to effect a cure. Whatever else may be obscure in the life of Paracelsus it seems quite certain that he was able to relieve diseases the curbing of which was beyond the powers of the regular medical system. It also seems probable, and is directly asserted by Boerhaave, that Paracelsus's medical fame lay in his skill in surgery and in his daring use of remedies, including chemical remedies, which were outside the list of those permitted to the physicians of his time. He was able to effect at least a temporary cure of Frobenius, and by the influence of his patient, and of that of Œcolampadius (who was professor of theology at Basle) and of Erasmus, who was then staying with Frobenius, Paracelsus was appointed professor of medicine at Basle. There is no evidence that he lectured there on chemistry.

For various reasons the stay at Basle was a short one. Paracelsus gave offence by lecturing in German instead of Latin, by abusing the old medical authorities and ridiculing—even it is said publicly burning—their writings, and by litigation with influential persons about his fees. After two years he was forced to leave Basle in disgrace. Thereafter much of his life was spent in precarious circumstances and in moving from place to place. He seems, however, often to have been treated with respect and to have enjoyed the acquaintance and hospitality of prominent citizens, but he also experienced poverty and met with contumely and contempt, which he knew how to return in kind. His arrogance and violence are beyond doubt, but these should not influence us in forming an estimate of his ability or in seeking for evidence of his solid achievements. He constantly emphasizes the futility of mere professional ritual, and in contrasting the silk-clad doctor spending his time cultivating the benevolent interest of the influential, with the alchemist working in his laboratory in a leather apron, he pointed the way which so many since his time have found it necessary to tread if any real progress is to be made. His insistence on the experimental method as contrasted with reliance on tradition is clear, and he is justly regarded as one of the great reformers of medicine.

After his official position came to an end, Paracelsus seems to have spent much of his time writing, and several important works were published in his lifetime. After his death, what were regarded as his genuine works were collected and edited by Huser and published in ten volumes during 1589–1591. This edition is the basis of all later ones and was prepared with unusual care and skill.

The whole works have recently been edited by Sudhoff, the foremost authority on Paracelsus, and at least fourteen volumes of this edition have appeared. Besides his genuine works there are several, mostly of an alchemical or mystical character, which are regarded as spurious, and it is on the basis of these that many unfavourable estimates of his character and beliefs have been based. In his case, however, apparent contradictions in separate works have little weight in deciding their authenticity. Apart from editions of his works there has been a really tremendous literature on Paracelsus, and a Paracelsus Society was recently established in Germany. A summary of the literature on Paracelsus and an appreciation of his contributions to science have recently been given by Dr. A. F. Titley in *Ambix* (the journal of the Society for the Study of Alchemy and Early Chemistry; 1, No. 3; 1938).

The reasons for this great interest in Paracelsus are various. The historians of medicine turn to a study of the reformer, whose violent methods recall and were probably modelled on those of his contemporary and countryman Luther. The historians of chemistry are anxious to find some justification for the claims that Paracelsus was of importance in their science. Those wider circles interested in the occult and superstitious find in his chaotic writings, not excluding the spurious ones, much of interest in their field. The man himself has formed the subject of poetry and romance.

The genuine writings of Paracelsus which appeal especially to the historian of science are the "Archidoxa" (of which an English translation appeared in 1663) and the "De Natura Rerum", which contain much of interest but nothing which can reasonably be said to constitute a definite advance in scientific knowledge. They emphasize that the main task of alchemy is not to make gold and silver but to prepare powerful remedies, and this certainly had a good influence on the development of chemistry and pharmacy. Many new mineral remedies, such as preparations of antimony, appeared as a result of this redirection of effort, but it has been emphasized above that Paracelsus had precursors in this field. An important feature of his teachings was his insistence that from a large bulk of inert material there could be extracted some small potent quintessence or arcanum in which the virtue of the medicine is concentrated (a view which is emphasized in the "Alchymia" of Libavius in 1597), but this idea again is to be found in the works of Arnald of Villanova and in the treatises attributed to Raymond Lully. The great stewpans of broths and messes of the Galenic and Arabian medicine gave way after Paracelsus's time to the small stoppered phials of the chemical pharmacist, and if some of these, with their arsenical and mercurial contents, were to wreak havoc in the hands of less-skilled practitioners, the ultimate gain was real and permanent. Many of his younger followers were men of great ability and he certainly inspired much valuable and enduring work in chemical pharmacy.

The writings of Paracelsus are very difficult to read and more difficult to understand. They provide an excuse for the charge frequently made that he was a charlatan, but when allowance is made for his extraordinary style they reveal his sincerity and receptiveness. They abound in strange words, but the terminology of contemporary medicine was far from perfect or adequate. They contain much which is superstitious, and material concerned with magic, charms and amulets, which is not really a new feature but a sediment from long-established medical practice. There is little of scientific interest, apart from a few vague remarks on mining and metallurgy and a mention of zinc, all of which is miner's gossip. There is much hinting at wonderful new chemical remedies, but no intelligible accounts of experiments by which they were discovered or processes by which they were prepared. There is no indication that Paracelsus did make any experiments in chemistry on scientific lines, although tradition, some of it good, suggests that he did. The views that the chemical information in the works attributed to Basil Valentine is due to Paracelsus, and that some of the important views found in the writings of Van Helmont are really his, will not bear close examination. His writings contain a great deal of boasting and harsh judgments of the physicians. Some allowance must be made for this. Paracelsus was certainly ahead of most of his plodding contemporaries, and his eager reforming zeal irritated them into malicious attempts to undermine his authority and bring him to contempt. This must have exasperated a man with much less patience and restraint than he possessed, and in circles where so much bitter opposition was met a violent reaction is only to be expected.

Where so few actual scientific contributions can be found it is perhaps a fair estimate of Paracelsus's merit in science to say that he pointed the way along which fruitful progress could be made and showed that nothing can be achieved by reliance on tradition in itself. He gave hints which in the hands of his followers came to fruition. He is regarded as the originator in chemistry of the famous theory of the three "hypostatical" principles, mercury, sulphur and salt, which Boyle said were professed by the "vulgar spagirists" of his time. Of these three, two and the most important, mercury and sulphur, were very much older than Paracelsus's time, although they had not been regarded as so widely distributed as he assumed;

and his salt is such a vague entity that it can scarcely be said to have any value in chemical theory. Still, some link may be traced between this *tria prima* and the three 'earths' of Becher, which led in turn to the phlogiston theory, an important phase in the development of theoretical chemistry.

In calling to memory the death of Paracelsus at Salzburg on September 24, 1541, we can point to little which is definite in his scientific contributions, but his insistence that Nature has little regard for theoretical systems or cherished traditions is essentially scientific and certainly played a part in the progress which was to lead to the "Sceptical Chymist" of Robert Boyle, a work in which Paracelsus is respectfully quoted and criticized. It seems that much of the fame of Paracelsus (like much of the discredit which is attached to his name) rests on popular estimates, and his contributions are not nearly so important as those of men whose names are practically unknown. It is probably certain that but for his emphatic lead the advances in chemistry which followed him so closely would have been deferred, and he well deserves a place in the annals of science quite apart from his contributions to medicine.

P. S. PALLAS (1741-1811)

By Eng.-Captain E. C. Smith, O.B.E., R.N.

ON September 22 occurs the bicentenary of the birth of Peter Simon Pallas, one of the greatest naturalists and scientific explorers of the eighteenth century. Though German by birth, he passed forty-two years in the service of the Russian Government, and the most fruitful part of his life was the six arduous years, 1768–1774, which he spent exploring the eastern parts of European Russia and the plains and mountains of Siberia.

The son of a surgeon, Simon Pallas (1694–1770), he was born in Berlin, and after studying at Halle and Göttingen graduated in medicine at Leyden. He then spent about a year in England examining and studying zoological collections and afterwards at The Hague published his first work on zoology. It was, however, not long before a more active career opened before him. In 1768, at the age of twenty-seven, he accepted the invitation of the Empress Catherine II to occupy a chair of natural history in the Imperial Academy of Sciences, St. Petersburg, and this led almost immediately to his appointment to an expedition being sent out, first to observe the Transit of Venus of 1769, and secondly to gather information about the peoples, plants, animals, climate and geography of the vast dominion of Siberia and of other little-known parts of the Russian Empire.

Scientific expeditions by land and sea under official auspices were a feature of the eighteenth century, and most of these expeditions were fostered by the Royal Society of London, the Paris Academy of Sciences and similar bodies. Among such expeditions was that made during 1733–1743 by Behring, J. G. Gmelin, G. F. Muller, S. Kraschenìnnikof and others for the Russian Government; this added immensely to the knowledge of northern Asia from the Urals to Kamchatka. Two years after this expedition set out the Paris Academy of Sciences sent Bouguer, Godin and La Condamine to Peru to determine the figure of the earth, while others were sent to Lapland. The Transit of Venus of 1761 saw other expeditions. One of these was carried out for the Paris Academy of Sciences by the Abbé Jean Chappe D'Auteroche (1722–69), who observed the transit at Tobolsk, the capital of Siberia. When this astronomer published an account of his travels he made some remarks about the state of Russia which led Catherine, who had literary leanings, to reply in a brochure entitled "Antidote contre le voyage de l'abbé Chappe".

As the 1769 Transit of Venus approached, Catherine determined to arrange expeditions second to none, and the Imperial Academy of Sciences, most of whose leading members were foreigners, was asked to draw up full instructions. Altogether seven astronomers and five naturalists with several assistants were attracted by Catherine's offers. The Swiss astronomers, J. A. Mallet (1740–90) and J. L. Pictet (1739–81), were sent to Lapland; the German scientific worker, W. L. Kraft (1743–1814), to Orenburg; the Russian mathematician and geographer, S. Rumoffski (1734–1815), to the Pola peninsula: and G. M. Lowitz (1722–74) to the Volga district. To the south-west of Russia were also sent the naturalists, S. G. Gmelin (1743–74), nephew of J. G. Gmelin, and J. A. Guldenstaedt (1745–80). Pallas himself left St. Petersburg in June 1768, spending the summer in the Russian plains and wintering at Simbersk on the Volga. He next visited Tartary, examined the shores of the Caspian, and in 1770 crossed the Urals to Catherinenburg. Having examined the mines in the district he went to Tobolsk and in 1771 visited

the Altai mountains. Proceeding north, he reached Krasnojarsk, on the Yenisei, and then turned back to the frontiers of China and so in 1773 to Astrakhan, where he met Gmelin. After visiting the Caucasus, he reached St. Petersburg again in July 1774. Lowitz and Gmelin were not so fortunate, for in that year the former was murdered by rebels and the latter died through illness and imprisonment while still carrying out exploration on the shores of the Caspian.

Partly during the expedition and partly afterwards Pallas published in German his "Voyages in Different Parts of the Russian Empire, 1768–75". "Few explorers", said von Zittel, "have contributed such a vast wealth of geographical, geological, botanical, zoological and ethnological observations as Pallas has done in this justly famous work." Another result of his travels was his book on the formation of mountains, his views on this subject giving him a place beside de Saussure as one of the founders of geology.

In 1793, Pallas commenced a journey of two years duration in southern Russia and the Crimea, and liking the district well, in 1795 he settled there on an estate given him by the Empress not long before she died. Here at Simferopol he passed fifteen years, continuing his studies in natural history. In 1810, after the death of his wife, he obtained permission from Alexander I, whose tutor in science he had been, to return home, and he died at Berlin on September 8, 1811, within a few days of his seventieth birthday. Of all the many eminent men of science, such as Delisle, Euler, the Gmelins, Daniel Bernoulli, Lexell, Æpinus, Lehmann, Nicolas Fuss and John Robison, whom succeeding Russian rulers attracted to St. Petersburg, none did greater service for their adopted country than Pallas.

POULTRY AS FOOD CONVERTERS

By E. T. Halnan,
Animal Nutrition Institute, Cambridge

THE value of the egg as a constituent of wartime dietaries, particularly for children, has to some extent been overshadowed by the insistence placed on milk as a perfect food. In point of fact, milk is not a complete food, being deficient in iron and relatively low in vitamin D, although rich in calcium salts. Eggs, on the other hand, have a poor calcium content, but are rich sources both of vitamin D and iron.

Both products are of high biological value, and are in a sense complementary to one another, mixtures of these two forming a perfect diet for young growing animals. Thus De Sanctis[1] reports the case of a three-months-old infant failing to gain weight on a whole-milk dextrimaltose formula, but responding and giving 8–12 oz. gains weekly when one teaspoon of soft-boiled egg yolk was added daily. Tweddell[2] similarly got satisfactory responses in two infants aged eight and nine months respectively by the inclusion of one raw egg daily in their milk diet. Hess[3], in efforts to combat rickets in babies, used egg yolk with marked effect, and recommends the inclusion of the yolk of a raw egg daily in the milk formula of a three-months-old infant as good routine practice.

The essential point to note in these cases is the failure of milk to prove adequate in the diets of some infants, and the power of egg yolk to correct its inadequacy. Moreover, both eggs and chicken meat are easily digested and readily tolerated by those with weak digestions, consequently they form essential articles in the diets of those recovering from illness. In addition, the hæmoglobin-forming power of eggs in cases of war-wounded patients suffering from loss of blood should not be overlooked.

On dietetic grounds therefore, the maintenance of an adequate egg supply appears to be just as vital to the health of the nation as the maintenance of an adequate milk supply. If, however, the home food production policy of the Government is considered, it would appear that this fact has not hitherto received the consideration that it merits. The shortage of animal feeding-stuffs, particularly concentrates, led the Government shortly after the outbreak of war to assign an order of priority to various classes of farm livestock for such feeding-stuffs as were available. Several factors appear to have influenced the final decision, among which may be named the relative efficiencies of the various classes of livestock as converters of animal feeding-stuffs to human food, the need for maintenance of land fertility, the fact that the foods normally fed to pigs and poultry largely consisted of materials available for direct human use, and the fact that the Scandinavian and the Low Countries were then available as sources of supply for eggs and pig products. As the result of these and

possibly other considerations, the final order of priority was: (1) dairy cows (as milk); (2) sheep and feeding cattle; (3) pigs for meat production and poultry for egg production.

It may be as well to point out that the Government of 1918[4], faced with a similar situation, placed the order of priority as follows: (1) working horses: (2) dairy cows; (3) breeding stock. Some allowances were to be made to pigs and poultry and breeding ewes, but none to fattening sheep or fattening cattle. The present order of priority for feeding-stuffs has caused the false impression to arise that both pigs and poultry are wasteful converters of feeding-stuffs; moreover, statements have appeared in the Press to the effect that this is the considered opinion of men of science. It may, therefore, be as well to consider the available evidence on this point.

At the present time the main problem that appears to be facing Great Britain so far as food supply is concerned is a prospective shortage of food proteins, particularly those of high biological value. The most efficient use of animal feeding-stuff protein for the production of human food protein consequently appears to be called for, and our considerations may therefore be conveniently directed to this issue.

In 1939 I made a careful estimate of the relative efficiencies of the various classes of farm animals as converters of feeding-stuff protein to human food protein. In this estimate, 100 lb. of digestible feeding-stuff protein yielded the following amounts of food protein available for use by humans: (1) dairy cow (as milk, yield 600 gallons a year), 35·8 lb.; (2) hen (as eggs, yield 140 eggs a year), 31·6 lb.; (3) pig (as pork), 21·2 lb.; (4) hen (as meat), 18·0 lb.; (5) bullock (as baby beef), 7·8 lb.; (as Norfolk beef), 5·9 lb.; (as grass beef), 5·4 lb. Owing to the absence of adequate data no estimate of the value of the sheep as a converter of feeding-stuff protein was made; but the opinion was given that, whereas grassland sheep production should be encouraged, arable land sheep should be discouraged, since in the latter case the land required for sheep keep could be better utilized for the production of grain and vegetables for direct human consumption. This memorandum was submitted to the appropriate Government departments and doubtless received due consideration. More recently, Leitch and Godden[5] have presented a report on the point at issue, after consideration of all the available scientific data. Placing their results in order of priority so far as efficiency of conversion of feeding-stuff protein to human food protein is concerned, we get the following results: 100 lb. of protein equivalent yield (1) dairy cow (as milk, yield 2 gallons a day), 35·1 lb.; (2) hen (as eggs, yield 200 eggs a year), 26·4–29·8 lb.; (3) hen (as meat), 21·8–26·3 lb.; (4) pig (as pork), 19·0 lb.; (5) baby beef, 15·5 lb.; (6) sheep (as lamb), 13·2 lb.; (7) fat bullock, 8·7–8·9 lb.

Although arrived at by different methods of computation and from different sources, it is of interest to note that roughly the same order of priority is reached by these authors as by my earlier estimate, and gives confidence in the view that the order of priority so established is in accordance with actual fact.

Regarded strictly, therefore, from the point of view of efficiency of conversion of feeding-stuff protein to human food protein, the hen as an egg producer would appear to rank in order of priority next to the dairy cow, and judged on this ground alone the hen has a better claim to available food supplies than any class of farm animal other than the dairy cow. Moreover, the results obtained indicate that the decision of the Government in 1918 not to allot supplies of feeding-stuffs to fattening sheep or fattening cattle was justified.

OBITUARIES

Sir Shah Mohammad Sulaiman

As chief justice of the High Court at Allahabad for several years and as vice-chancellor of the Aligarh Muslim University over a considerable period, Sir Shah Sulaiman was a well-known public figure in India. During the last few years of his life he held the distinguished position of one of the three judges of the newly established Federal Court at Delhi. The news of his death early this year at the age of fifty-five came as an unpleasant surprise to his many friends and admirers, and elicited numerous well-merited tributes to his personality and career.

Sulaiman studied mathematics and physics at Cambridge, taking Part II of the Mathematics Tripos in 1909. During his subsequent career as a practising barrister and as a judge at Allahabad, he continued to retain a general interest in the progress of physical science. Later in life, the stimulus of contact with the University staffs at Allahabad and Aligarh led him actively to undertake the study of theoretical physics as a subsidiary pursuit.

Sir Shah's high position in public life secured for his writings and lectures on scientific topics the widest publicity in India, as also a sympathetic, though critical, reception from his academic friends and colleagues. His published papers indicate a marked reluctance to accept the ideas of the newer physics as expounded by the leading authorities on the subject. They largely consist of attempts to explain the facts of the newer physics on the basis of classical or semi-classical ideas aided by special hypotheses. It could scarcely be hoped that work on such lines would find general acceptance.

Sir Shah Sulaiman was the recipient of honorary doctorates from the Universities of Allahabad and Aligarh in recognition of his eminent public services and his deep interest in the cause of education and science. C. V. RAMAN.

Mr. W. A. Taylor, O.B.E.

THE death occurred on August 18 at St. Albans at the age of sixty-eight of Mr. W. A. Taylor, a former superintending examiner at the Patent Office.

After spending eight years at the railway works at Crewe, Taylor obtained a Whitworth scholarship and proceeded to the Royal College of Science, from which he entered the Patent Office as an assistant examiner in 1897, at the age of twenty-five. During the earlier part of his career, he dealt with inventions relating to gearing and clutches. In 1915 he was loaned to the Munitions Inventions Department where he was particularly associated with the early development of the tank and with experiments on body armour, including head protection by steel helmets.

Returning to the Patent Office at the end of the War, he was placed in charge of one of the examining divisions in 1925, and from 1927 until his retirement in 1936 was superintending examiner in charge of classification, during which time he made his main contributions to the work of the Office. Under his direction a separate classification division, akin to that existing in the United States Patent Office, was set up, and he was responsible for the amalgamation of the unclassified series of illustrated abridgments, which had appeared weekly in the *Illustrated Official Journal of Patents* from the time of Mr. Chamberlain's Patents Act of 1883, with the classified series which had been published at intervals from 1894 onwards. By this reform, the classified abridgments were issued sheet by sheet in forty group-volumes within a few weeks of acceptance of the specifications instead of after a period of many months. Another important duty undertaken by Taylor was the setting up of machinery for carrying out the extended search for novelty instituted by the Patents Act of 1932 by which United States specifications and other publications were brought into the field of search.

In the difficult and controversial subject of the classification and indexing of the subject-matter of inventions, Taylor was an advocate of the analytical method and favoured the collection of data relating to materials and machine elements of general application.

He took an active interest in the welfare of the staff and was for some years chairman of the Examining Staff Association. Apart from his activities in the Office, he had many interests in the realms of music, education, sport and travel, and his generous nature and human attitude to affairs gave him a wide circle of friends.

Mr. J. Duncan

THE death of John Duncan on July 28 will be regretted by the many engineers, all over the world, who have at some time been his students. He was seventy-two years of age and had for several years suffered severely, although in the end, the acute stage of his illness lasted only a few days.

Duncan went to Hutchinson's Grammar School in Glasgow, his birth-place, and his early training in engineering was received at the works of Messrs. Duncan Stewart & Co., Ltd. He studied at the Royal Technical College, Glasgow, and then in the University of Glasgow. From there he was appointed, in 1896, as lecturer in engineering at University College, Nottingham. In 1898, at the opening of the Municipal Technical Institute at West Ham, now the West Ham Municipal College, he was appointed lecturer in mechanical and civil engineering, and after a short time became head of the Department of Engineering. His organizing ability soon showed itself, for a set of empty rooms quickly became a department excellently equipped both in staff and machinery.

On the reconstitution of the University of London in the early years of the century, Duncan was made a 'recognized teacher' in the University in engineering, being one of the first so appointed. He served on the Board of Studies in Engineering in the University until his retirement from teaching in 1929, and on many occasions was examiner in the subjects of engineering.

Duncan's lectures and practical courses at West Ham were always the admiration of his colleagues, for as well as being thoroughly skilled in practice and draughtsmanship, he had a wide knowledge of theory and always spurred on his students in the mathematical side of their work. His clearness of exposition will always be appreciated where the many text-books that he contrived to write during his busy career are used.

WE regret to announce the following deaths:

Prof. A. G. Green, F.R.S., formerly professor of tinctorial chemistry in the University of Leeds, and director of research to the British Dyestuffs Corporation, on September 12, aged seventy-seven.

Mr. John Still, formerly secretary of the Ceylon Association in London and an authority on the antiquities and natives of Ceylon, on September 9, aged sixty-one.

Dr. Guy Wood, who had been honorary treasurer of the Marine Biological Association of the United Kingdom since 1934, on September 4.

NEWS AND VIEWS

British Association: Science and World Order

FURTHER information is now available concerning the conference on "Science and World Order" to be held under the auspices of the British Association (Division for Social and International Relations of Science) during September 26–28, at the Royal Institution (see p. 331 of this issue).

The First Session, under the chairmanship of Sir Richard Gregory, president of the British Association, will deal with "Science in Government". It will deal with the use of scientific men and scientific methods within departments of Government, and with the development of Government research. Prof. A. V. Hill will describe the use which has been made of scientific workers, and the way in which co-operation and collaboration has been secured in Britain and between Britain and the United States. Prof. J. D. Bernal will deal with the shape of scientific organization within Government service, and its possible future development. A French representative will be asked to deal with the organization of science in France before the War. It is hoped that the Chinese representative will deal with the development and encouragement of scientific organization behind the lines and under stress of war in China, and that a Russian representative will outline the important part which science has played in the development of the U.S.S.R.

The Second Session, under the chairmanship of the United States Ambassador, Mr. Winant, will deal with "Science and Human Needs". Sir John Orr will be dealing with food in terms of the advance in the science of nutrition, of the work which has been done in the form of surveys of food requirements of various countries, of the inadequacies, and of the means, which science offers, of raising the standard of nutrition throughout the world. Sir Harold Hartley, speaking on "Power", will discuss the development of the natural resources of the world to secure the maximum benefit. An American representative will probably deal with the harnessing of power to the new amenities of life.

The Third Session, under the chairmanship of the Russian Ambassador, Mr. Maisky, is concerned with "Science and World Planning". An American representative will deal with large-scale projects, such as the Tennessee Valley development, illustrate the plan behind it, and the future of such development. Prof. Sargant Florence will discuss the redistribution of the population, which has been made possible by electrification, but which, without planning, may equally lead to even greater concentration in conurbations. Other speakers will relate similar examples to the general need for large-scale planning in terms of world reorganization.

The Fourth Session, under the chairmanship of Dr. Benes, President of the Czechoslovak Republic, will deal with "Science and Technological Advance". It will be concerned with the new processes, new materials, and new production techniques, which have been made possible by science and have been accelerated by war, and which, under planning, can mean the release of abundance, and without planning, will mean economic chaos.

The Fifth Session, under the chairmanship of the Chinese Ambassador, Dr. Wellington Koo, will deal with "Science and Post-War Relief". Representative speakers will concern themselves with: (1) the risks of epidemic diseases through war exhaustion, and the measures to counter them; (2) the risks of famine and the distribution of surpluses which are now being accumulated throughout the world; (3) 'scorched earth' problems of soil-rehabilitation. Others will deal with the development of backward and neglected areas.

The Sixth Session, under the chairmanship of Mr. H. G. Wells, will deal with "Science and the World Mind". The major problem is how to make the peoples and nations comprehend the meaning of scientific development and the ways in which these can be used for human betterment and social security. At the end of the conference, the president, Sir Richard Gregory, will put forward a new Charter of Scientific Fellowship.

University of Birmingham: Chair of Zoology

THE appointment of Prof. L. T. Hogben, F.R.S., to the chair of zoology in the University of Birmingham, represents a serious loss to the University of Aberdeen where, in the course of a short but fruitful tenure of the regius chair of natural history, he had built up one of the most attractive and active departments in Great Britain. Both at Aberdeen and Cape Town, Prof. Hogben adapted the policy of his department to fit in with local biological interests and exploited to the fullest extent the natural resources of the neighbourhood. At Birmingham he will find ample scope for similar activity, and his greater proximity to London will enable him to attend meetings from which his absence has, too long, been felt.

Among academic zoologists Prof. Hogben is distinguished for his well-known analysis of the pigmentary effector systems of vertebrates, particularly those of the amphibia; he has also made very important contributions to genetics. In both these fields he has had numerous students in Great Britain and elsewhere. In much wider fields Prof. Hogben is known as the author of "Mathematics for the Million" and "Science for the Citizen". Both of these books show not only a very remarkable width of vision but also a profound belief in the intelligence of the average man. At Birmingham, Prof. Hogben will find a fertile field, well tilled by his predecessor, Prof. H. Munro Fox, F.R.S. (NATURE, June 28, p. 800), and of the abundance of the crop he will reap there can be no doubt.

The Generic Names Fenestella and Fenestrellina

Dr. G. E. Condra and M. K. Elias, of the University of Nebraska, have sent a notification to the Editors of NATURE of a proposal to preserve the generic name Fenestella. The following is an abstract of the document:

The International Commission on Zoological Nomenclature is asked to suspend the Rules of Zoological Nomenclature in the case of *Fenestella* Lonsdale, the well-known genus of late Palæozoic Cryptostomatous Bryozoa, and retain this name as a *nomen conservandum*. The history is as follows: *Fenestella*, Bolten, 1798, for a Lamellibranch Mollusc; synonym of *Anomia* Linnæus, 1758; *Fenestella*, Lonsdale, 1839, for a Cryptostome bryozoan; genotype *F. plebeia* McCoy; *Fenestrellina* d'Orbigny, used by Bassler for the pre-occupied name *Fenestella* Lonsdale. But the genotype of *Fenestrellina* d'Orbigny is *Fenestella crassa* McCoy, which is not congeneric with *Fenestella lebeia* McCoy. Therefore a new name is needed for the genus *Fenestella* Lonsdale *non* Bolten, unless the Rules of Zoological Nomenclature are superseded, and *Fenestella* Lonsdale is conserved. In order to avoid a new name, and because it is in every way desirable to conserve the well-known, wid ly adapted, and long-established Bryozoan genus *Fenestella*, it is asked that the Rules of Zoological Nomenclature be suspended in this instance, and *Fenestella* be kept as a *nomen conservandum* for the Bryozoan genus.

The University of London

THE report of the Principal on the work of the University of London during 1940–41 is distressing testimony to the wanton destructiveness of modern warfare. The wisdom of the policy of dispersal, which at one time aroused criticism, has been fully borne out by the widespread damage that many of the University buildings have sustained from air raids. This damage has already been described in NATURE. The teaching staff of the University has lost the services of eighty-six professors and readers, who together with many other teachers are now engaged in various forms of war work. Owing to the claims of national service the roll of internal students in the second year of war is expected to show a fall of about 40 per cent. Nevertheless, in spite of all difficulties, the essential work of the University has been carried on in a most remarkable manner. Except for certain readjustments necessitated by war conditions, no significant changes have been made in the curriculum, and examination standards have been fully maintained.

The complete range of external examinations was carried through under the scheme of decentralization. In the first year of war, external examinations were held in some forty centres overseas, and more than 1,200 students were examined. Although this operation involved the distribution of very many printed papers, and the collection of some thousands of scripts only two scripts were lost as a result of enemy action. The work of the University for its External Students has been fully maintained, in fact, in certain directions the University has extended its activities. Some hundreds of students now serving in different branches of H.M. Forces have received assistance in continuing their work for degrees. Educational contacts have been established with Allied personnel now in Great Britain, and through the Red Cross even prisoners of war in Germany have been enabled to keep their intellectual interests alive.

Among several benefactions received during the year, the University was given an endowment by the Clothworkers' Company for a William Gilles fellowship for research in science, to the value of £220 for one year, to be awarded biennially. Dr. T. H. Sanderson-Wells has provided funds for the endowment of an occasional Sanderson-Wells Lecture, on human ailments with special reference to soil fertility. Mrs. E. L. Hamilton has presented to the London School of Hygiene and Tropical Medicine £1,500 to be used in the prevention of disease in the tropics. Developments in educational policy and organization are of necessity in abeyance, but in one direction at any rate useful preparatory work has been done, for an influential advisory board has been set up to report on the co-ordination and extension of Colonial studies and researches, for which support may be forthcoming from the Colonial Office as part of the Government plans arranged early in 1940.

Plastic White Lines for Roads

THE majority of the white lines applied to road surfaces for aiding traffic flow are prepared with white paints made from pigmented solutions of Manila resin in alcohol; such paints are the subject of Specification BS/ARP 38. Attention has recently been given to alternative white-line materials by the Paint Research Station and the Road Research Laboratory. According to *Roads and Road Construction* of September, one of the most promising alternatives is a thermo-plastic material applied hot to the road surface as a thin layer which sets hard on cooling. This type of material has the advantage that its set does not depend on evaporation of a volatile constituent; it hardens rapidly, allowing traffic to pass over it within a few minutes of application. It has good wear resistance and maintains a reasonably white colour. Thermoplastic materials of a proprietary type have been subjected to road tests during the past two years and in some instances have given satisfactory results. The composition now described is suitable only for open- and medium-textured road surfaces which provide a certain amount of key or mechanical grip. It may be applied to an existing road surface without insetting. A specification has been drawn up for the manufacture and application of the composition.

During the past year, trials have also been made with a number of compositions based on a light-coloured binder compounded with a white filler and a high proportion of a light-coloured sand or other fine aggregate. The filler is a mixture of equal weights of finely divided silica and the pigment titanium oxide. The binder consists of 80 per cent by weight of rosin, the remainder being crude wool grease. This composition can only be applied during spring and

summer months, in warm, dry weather. The composition is now under test; it is in satisfactory condition after five months on a busy trunk road and after ten months on a by-road, and from the results of these and other tests, a useful average life of at least six months may be expected. The colour, while not so white as that of newly painted white lines conforming to BS/ARP 38, nevertheless gives a good contrast with the road surface when observed during day- and night-driving and does not degenerate appreciably.

Health of Southern Rhodesia

IN his recently published annual report for 1939, Dr. Andrew Paton Martin, medical officer of health for Southern Rhodesia, directs attention to the decrease in the birth-rate, the increase in venereal disease and the infiltration of tuberculosis in the colony. There has been an appreciable decrease in scurvy in the mining natives, but the methods of feeding the employees are still far from satisfactory. Of the tropical diseases prevalent in Southern Rhodesia malaria is the most serious, as it caused 10 per cent of the deaths in 1939. Bilharziasis followed it close, and leprosy is a big problem, but trypanosomiasis seems to be absent.

Earthquake in Turkey

A SERIOUS earthquake with its epicentre near Agri, some 70 miles east of Erserum in Turkey, was reported on September 12. Full details are not yet available, but it is feared that the death roll may amount to 500. It will be remembered that the most severe earthquake ever experienced in Turkey took place on December 27, 1939 (see NATURE, January 6, 1940), in Anatolia, and serious aftershocks have occurred at intervals since that time. It may be that large fault blocks in the area have not yet attained their final position of equilibrium, and that parts of the subcrustal layers may still be under some elastic strain.

Earth Tremor in Scotland

ON September 6 an earth tremor shook the Stirling district in Scotland. Furniture was moved by the shock in the villages of Cambus Barrow and Whins o'Milton, but no damage is reported. Stirling district experienced a previous tremor on the night of February 2–3, 1940 (NATURE, February 10, 1940).

Bequests to the University of Sydney

THE University of Sydney has recently received a bequest of £60,000 from the estate of the late Sir Hugh Denison. This bequest is particularly valuable as it is for general scientific research, and unconditional.

The McGarvie Smith Institute of Sydney has made a grant of £9,000 in addition to earlier grants for the extension of the equipment facilities of the Animal Husbandry Farm which bears its name, and which forms an important part of the equipment of the Faculty of Veterinary Science of the University.

Awards of the Medical Research Council of Ireland

THE Medical Research Council of Ireland has made the following awards during the half-year ended June 30, 1941: *Training grants:* Miss D. A. Kilbride for one year from August 1, 1941, to carry out an investigation of iodine absorption by means of balance experiments; and Miss E. O'Donovan for one year from June 1, 1941, to assist in the investigation of the goitre problem by studying the retention of iodine under varying conditions of diet, the work in both instances to be done in the Department of Chemistry, University College, Cork, under the direction of Prof. J. Reilly and Dr. E. M. Mason; *Whole-time grant:* Dr. Cecil Mushatt for four months from March 1, 1941, to enable him to continue his research work at the Johns Hopkins Hospital; *Grants-in-aid:* Dr. James Deeny for six months from July 1, 1941, to investigate the relationship of vitamin C to the formation of complement and the relationship of both to immunity; Dr. D.K. Malley, to investigate the effects of the cortical hormone on a case of pre-adolescent type of adrenocortical syndrome; and Dr. J. G. Waugh, towards the expenses of his research work on sulphonamide therapy in the School of Physic, Trinity College, Dublin. The following grants have been renewed for one year: Dr. T. E. T. Bradshaw (from March 1, 1941) and Prof. Hans Sachs (from May 1, 1941). Prof. J. B. Gatenby and Dr. R. G. Cross have relinquished their grants.

Announcements

THE medal of the U.S. Society of Chemical Industry has been awarded to Dr. Elmer K. Bolton, chemical director of the E. I. du Pont de Nemours and Company, in recognition of his work in connexion with the development of Neoprene, Nylon and synthetic rubber.

DR. JEROME C. HUNSAKER, head of the department of mechanical engineering in the Massachusetts Institute of Technology, has become co-ordinator of research and development for the U.S. Navy. He will be assisted by a special board, to be composed of representatives of the chief of naval operations and the commanding officers of the Bureaux of Ships, Ordnance, Aeronautics and Yards and Docks.

PROF. WILLIAM F. DURAND, emeritus professor of mechanical engineering at Stanford University, has been appointed a member of the U.S. National Advisory Committee on Aeronautics. He succeeds Dr. Robert E. Doherty, president of the Carnegie Institute of Technology, who resigned his membership on July 3 to become chairman of the Production Planning Board of the Office of Production Management.

THE following appointments have recently been made in the Colonial Service: D. U. Peters, agricultural officer, Northern Rhodesia; H. A. M. Thompson, agricultural officer, Sierra Leone; C. O. Flemmich (assistant conservator of forests, Malaya), conservator of forests, Fiji.

"The Philosophy of Physical Science"

THE correspondence on this subject provides a most enlightening example of the present transition in scientific philosophy from the view that science is a description of an objective external world to the view that it is a formulation of the relations found between experiences. Thus, to Sir James Jeans[1], taking the older view, light is an objective entity the velocity of which is either finite or infinite, while Sir Arthur Eddington is interested only in the fact that, since our experiences could be correlated equally well or ill by postulating an infinite or an immeasurably large finite velocity, the possibility of the former can be ignored. It is not surprising that, as Sir James rightly complains, Sir Arthur has not answered his objections. They are meaningless in Sir Arthur's philosophy, and he cannot reply in applicable terms.

I have long been convinced that the view which Sir Arthur now accepts is necessary to make sense of modern (or even older) physics, and have ceased to regard the question as a controversial one. Nevertheless I am equally convinced that Sir Arthur has not grasped the true implications of the new conception, and that Sir James's objection, though stated in terms meaningless to Sir Arthur, is both valid and unanswerable. If we can imagine an alternative experience to that which a law requires, then that law is not logically necessary. There is no escape from that, and if the unexpected should happen, we have to decide between giving up the law and denying the experience. There is no question which is the scientific choice.

It is, however, most desirable to locate the fallacy in Sir Arthur's reasoning. His programme for science is as follows: (1) Construct a scheme of pure reason based on a few *a priori* postulates. (2) Make observations and describe them in terms of those postulates. (3) Draw up a table of correspondences between the elements of the rational scheme and the observations: since the scheme is logically coherent, the corresponding observations must then be logically necessary if the original postulates really lie "at the bottom of things". Hence (4) find criteria for determining that the postulates are so basic. Those criteria having been found, the logical necessity of experience is assured.

The fallacy is, I think, that such criteria cannot exist, because, "in our limited view, at the bottom of things" lies not necessary postulates but experience, and experience is not yet complete. Take any "law of Nature" (for example, the law of gravitation). Deduce where Jupiter will be observed at some instant next year, and suppose that, when the time comes, Jupiter is seen elsewhere. If the law is *a priori* inviolable, Sir Arthur's only explanation can be that observations of Jupiter are not the experiences to which it applies. But if there are criteria for establishing the correspondence between law and observation, he is denied this explanation. What, then, is left to him?

Sir Arthur may be right in believing that his "epistemological" method is a short cut to discovery. Many a theory fundamentally unsound has given valuable guidance to knowledge, and it is certainly to be hoped that "structuralism" will do so. But that is trivial compared with its truth or falsity. As Sir James says, if Sir Arthur's theory is right "its consequences are tremendous—to physics, to philosophy and to humanity". No effort can be too great to clear the matter up, and if, as I believe, Sir Arthur is profoundly wrong, no protest can be too strong against an illusion which would destroy the very fundamentals of science and throw us back intellectually (and therefore socially, since ideas determine the state of our social life) into the dark ages.

It may be added that Sir James Jeans is incorrect in saying that the finiteness of the speed of light is an essential part of the theory of relativity. If that speed had been infinite the truth of the theory would never have been doubted; we should not have expected optical experiments to reveal the Earth's speed. The difficulty was to reconcile the null result of the Michelson-Morley experiment with the *finiteness* of the speed of light. But if that speed will not perform the service which Sir James asks of it, it provides us with a very convenient way of contrasting the alternative viewpoints. Sir Arthur Eddington says: "It is *a priori* necessary that the velocity of light is finite; therefore our observations of Jupiter's satellites could have been predicted and could not have been otherwise." Sir James Jeans says: "It is a fact of Nature that the velocity of light is finite; therefore Jupiter's satellites appeared in the positions which Römer explained". The scientific statement I hold to be this: "Jupiter's satellites were observed in certain positions. Therefore, if we attribute the observations to light travelling from the satellites to us, and assume that the satellites move according to Newton's laws, we must assign a finite velocity to that light".

HERBERT DINGLE.

Imperial College,
London, S.W.7.

[1] NATURE, 148, 140, 255 (1941).

MAY I first correct a slip in my last letter? In contrasting the actual and imagined results of the Michelson-Morley experiment, I absentmindedly interchanged them. I should have written, "It is a logical impossibility that the experiment should give other than a null result in the conditions *described*; but . . ."

Prof. Dingle asks us to imagine Jupiter seen away from its predicted place. Is it not simpler to substitute Uranus, for which this experience actually occurred? Adams and Leverrier rejected both of Dingle's alternatives. They neither gave up the law of gravitation nor denied the experience. They inferred that the system *pointed out* to the observer was not the system *described* to the calculator, a planet present in the former being omitted in the latter. Or, in Dingle's phrase, they amended the table of correspondences. His argument seems to me to fail because it assumes that when the unexpected happens only two courses

are open, surprisingly omitting the third course, which is the course a scientist usually follows. When an object gives an unexpected reaction, he does not rail against the laws of Nature; he concludes "Then it cannot be the object I thought it was."

The sources of gravitation (mass, momentum and pressure) are defined in the rational scheme by the tensor $G_{\mu\nu}-\frac{1}{2}g^{\mu\nu}(G-2\lambda)$, and it is an easy mathematical deduction that Einstein's law of gravitation and the laws of motion are necessarily and universally true; a failure of prediction can only mean that some gravitational source has been overlooked. This is non-controversial; but it is only a preliminary to a more disputed question, Would such a law be admitted as a law of physics, without an additional condition implying some special relevance to experience? My answer, which shocks many people, is that I cannot find that modern physics imposes any such condition of relevance on the laws which it accepts as fundamental. If there is a criterion, it should apply to all the fundamental laws. When we consider gravitation alone, a criterion of "simple application" suggests itself. However arbitrary may be the motion of the planets, Einstein's law will give a corresponding distribution of gravitational sources; but the actual sources in the solar system are few and discrete, and this unforeseen simplification makes long-range prediction possible. Ought we not to take cognizance of the fact that the law of gravitation has a much simpler application to experience than the formal theory suggests? I do not think we can; because the other fundamental laws have not this simple relation to experience. If we want a simple application of them, the experimenter must set his wits to work to create the necessary conditions. We can scarcely accept a criterion of fundamentality which is a function of the technical skill of the experimenter.

The widespread impression that the accepted laws are peculiarly fitted to actual features of experience is, I think, due to too much stress being laid on the historical development of science. Naturally the great advances are made when we find or contrive to create exceptionally simple conditions, so that disentanglement becomes relatively easy; thus the laws become historically associated with an artificial simplicity of experience which is by no means typical. Properly to understand the law of gravitation, we must forget the lucky circumstances of dynamical astronomy which probably accelerated its discovery by hundreds of years, and suppose that it has, for example, been patiently sorted out from an analysis of earthquake waves. In rejecting the criterion of simple application we must reject also the criterion of utility, which is evidently closely connected.

Another objection is that gravitational sources generally betray themselves by emitting or reflecting radiation; so that if Einstein's law indicates a source which we cannot find by radiation tests, something has probably gone wrong. But the finding of such a contradiction presupposes that we are treating gravitation and radiation disconnectedly. In unified theory the scheme of fundamental laws forms an interdependent whole, and we can only recognize agreement or disagreement (correct or incorrect correspondences) with the set of laws as a whole. The congruence of gravitational and radiative sources forms a difficult and technical part of the problem of unification; and it was not until I felt that I had cleared up the physical questions involved that I reached in my own mind the view under discussion.

I think then that the only necessary condition is that the fundamental laws shall form a single scheme, applicable to experience in the sense that all varieties of knowledge gathered by the methods of physical science can be formulated in terms of it. The choice is not limited by considerations of simplicity of application, utility, or appropriateness to the actual state of the universe, and is therefore left open to be determined by the *a priori* considerations described in my last letter. Dingle defends my view (up to a point) as "necessary to make sense of modern . . . physics". That expresses precisely the limits of what I am trying to do—not to make sense of experience, but to make sense of the assertions of modern physics. And the sense which I make of one set of assertions is that they are not assertions about experience at all. The continuation of Dingle's argument is obscure to me because I am unable to ascertain his orientation. In my "frame of reference" experience is at the top, and the physicist has been working his way down to so-called fundamental concepts at the bottom. Dingle upsets my frame by bluntly saying that experience is "in our limited view, at the bottom of things"; what is at the top of things is not stated.

"The Relations between Science and Ethics"

I WOULD like to make a reply to some of the very interesting comments on my article[1] on the relations of science and ethics. I will try to be brief although some of the questions raised are probably due to the brevity of the original discussion. I will not allude to all the points of agreement, which are actually more numerous than some of the writers suggested. Thus I entirely agree with Dr. Matthews that ideas affect societies; in fact I supported this point by a quotation from Engels.

There are two major issues: whether ethical principles are founded on our experience, and the problem of free will. In the former connexion the arguments of my opponents have been stated by Prof. Joad in a form which is so nearly a *reductio ad absurdum* that much of my work has been done for me. "I cannot understand", he writes, "how anything can be measured without a ruler which is external to and other than what it measures." By this he certainly does not mean merely that no system of mensuration is possible with less than two objects; for after all I am not suggesting that an ethical system involving different degrees of good would be engendered by a universe consisting of a single indivisible act. Nor, I presume, does he refer to the fact that our units of measurement, though roughly specified by the nature of the world, are in detail defined arbitrarily. His remark only provides a basis for his subsequent argument if it is taken to mean that we determine the relative sizes of objects by reference to some transcendental foot-rule reached down from beyond the boundaries of space and time. This, as we know from the theory of relativity, is untrue. The space–time framework is a function of the material objects lying within it. I might indeed have expressed my main contention by saying that, just as space–time issues from the material world, so the ethical system could be logically derived from our experiences. I may assure the Dean of St. Paul's that I am not urging that we should immediately

reject all ethical principles which we cannot in practice trace back to biological and sociological data, any more than I suggest that we should all learn enough mathematics to convince Sir Arthur Eddington that we fully understand the logical structure of an inch. I am merely concerned to show that the validity of ethical principles can be accepted even if we reject any criterion imported from outside the perceptual universe.

Joad again reduces to absurdity the view that there is an ethical criterion independent of experience by his statement that we all know (innately is implied by his argument) that "we ought to live very much as Christ enjoined". There are a thousand localities, from Dachau to Dahomey, where it is impossible to assert this with any plausibility. We prefer the ethical intuitions of Christ, Buddha or Socrates to those of Hitler or Rosenberg not because they are more mystical but because they seem more likely to carry society forward in the direction it has already taken. I see no grounds for rejecting the view which I put forward on the basis of psychological and anthropological evidence, that our tendencies towards sympathetic behaviour, although of sufficient strength to have enabled man to develop a degree of social existence, are nevertheless merely one of the general drives towards various unspecific forms of behaviour by which his conduct is affected.

The argument given above must serve, in the space available, as a reply to Prof. de Burgh, who demands an unconditional validity for my example of an ethical scientific statement, but is apparently willing to forgo it for the contrasted 'Thou shalt not kill', the ethical nature of which he would not deny.

The widespread disagreement with my argument about evolution is a continuation of the same dispute. In the first place, I am glad to find that the course of evolution has been revealed, not only to myself and Herbert Spencer, as Prof. Ritchie suggested, but also to Prof. Huxley; surely the attempt to repudiate the normally accepted evolutionary sequence on the grounds that certain primitive animals still exist is a forlorn crusade. But the crux is my statement that the direction of evolution is good simply because it *is* good. By that I meant that if the ethical system is to be derived from the nature of the experiential world, we must pay attention to what that world is like; and one of the most important data is the scientifically ascertained course of evolution. The remark about fatalism which followed was intended to indicate that the general trend may suffer temporary set-backs. Just as loss of structure due to parasitism, as in Sacculina, does occur but is not typical of the greater part of evolutionary change, so social regressions, of a spatially or temporarily limited nature, are easily conceivable. This point was expanded by Prof. Huxley, with whose remarks both here and in his valuable essay "The Uniqueness of Man" I am in substantial agreement.

Prof. Stebbing attacks an outlying bastion of my position in this field; not my actual discussion of evolution so much as my comments on T. H. Huxley's remarks about it. My "three different answers" to Huxley's argument were answers to three different questions. The first was a rejection of his description of its *methods*, the second of its *results*. In the third I countered the possible objection that, logical though my derivation of the good might at first sight appear to be, I had actually identified it with something which no one had ever dreamed of calling by that name. I was arguing that my conception was not only self-consistent but also not unrelated to the conventional meaning of "good".

A more difficult point is raised by those who suggest the possibility of a general and persistent regression, for example, by the operation of the classical second law of thermodynamics. I think that the difficulty, if it should at any future time actually arise, could only be got over by a theory of levels of ethics. One could distinguish a social good, dependent on a good derived from human individual biology, which again would be dependent on the effective principles of change in the physico-chemical world; and one would have to be content to deduce that a continual increase in physical good gives rise to an undulation in the development of biological good. But difficult though the problem undoubtedly is, that difficulty does not arise only on my theory of ethics; how can it be surmounted if ethical values are attributed to a beneficent deity?

The other fundamental disagreement, which relates to the problem of free will, was raised explicitly by the Dean of St. Paul's and Prof. de Burgh, and implicitly by several others. I confess myself unable to offer a satisfactory reconciliation of materialistic determinism and the efficacy of the human will; but again the problem is not one for my theory alone, and I shall be agreeably surprised if my commentators are in a much more comfortable logical position. I can only make one suggestion, with the greatest tentativeness. First, I suggest that it may be more profitable, in discussing this matter, to picture the human mind not as a simple mechanism of stimulus and response, but as containing a set of drives (each, figuratively speaking, a complicated motor) one or other of which can be set in motion by pressing the appropriate switch. In the decision whether, say, the sex or the nutritive drive becomes activated, the external stimuli not only reach directly for the switches, but also bring into play internal systems whose functions are also to affect the choice of which drive is selected. It may be that the sensation of an effort of will is no more than the conscious symptom of the activity of one of these internal systems, perhaps the super-ego or some part of it. If this part of the mind is, owing to the way in which it has been derived from the external world, normally effective in the direction taken by the evolutionary process as a whole, then could it not be argued that its conscious correlate is in fact indicative of a good impulse, quite independently of whether strict causation is violated or not? The peristaltic action of our bowels, although not under much conscious control, is good on my definition; may not the sensation of a deed well done be just as valid, on a higher plane, as the sensation of physical well-being after exercise and a bath?

Sept. 9.
C. H. WADDINGTON.

[1] NATURE, 148, 270 (1941).

DR. WADDINGTON's interesting essay which was published in NATURE of September 6, p. 270, suggests that he is still wavering between the theory that when you have explained a thing you have explained it away, and the fundamental but usually unspoken postulate of science that everything has an explanation, even though this implies an infinite series of causation. In Dr. Waddington's opinion, Marxists

say that ethical systems are epiphenomena which may be left out of account when we are considering the mechanism of social development. T. H. Huxley invented the word 'epiphenomenon' to mean a mental event caused by physical events, but not in its turn causing physical events. I believe that in the long run science has no room for such loose ends. Certainly Marxism has not. "It would be totally absurd", wrote Lenin in "Materialism and Empirio-criticism", "that materialism should maintain the 'lesser' reality of consciousness." Marxists hold that mind is real, but secondary to matter because matter existed before mind. Similarly, they think that economic and social structure largely determines the ethical system. "Thou shalt not commit adultery" is meaningless in a society with no marriage. "Thou shalt not steal" is replaced by "Thou shalt not waste" as property becomes socialized.

Given such a point of view, ethics must be fitted into our world picture, though we cannot yet see how in full detail. It is clear that ethical practices and ideas have a history, both in the development of communities and of individuals. Marxists have stressed the former process, Freudians the latter. This fact does not mean that ethics are arbitrary or baseless. England is real enough though it was once under the sea; vision is real though human embryos have no eyes. It does mean that we cannot act as rightly as possible without a study of contemporary history, which shows us what is alive and growing and what is vestigial in current ethical systems. Perhaps the careful attempts to isolate university staffs from the impact of history, if they have been advantageous to abstract speculation, have disqualified them from valid judgments on the highly concrete problems of right and wrong. The technique of modern warfare, which has broken down this isolation, may lead them to more realistic thinking on ethics.

A fuller study of the literature of Marxism might, I think, not only have shown Dr. Waddington that Engels stressed the importance of unconscious motivation before Freud, but also have made him more sympathetic to T. H. Huxley's thesis in "Evolution and Ethics". Stated in dialectical terms, it is that the cosmic process, which was responsible for human evolution, negates itself by generating the ethical process. The problem then arises of how man is to continue evolving if the congenitally weak are not killed off. Hitler's solution is substantially to abolish ethics. The correct solution will not be so simple. There is a real contradiction, which will be resolved when men not only realize, as eugenists do, that they ought to control their own evolution, but also possess, as they do not at present, the knowledge and technique necessary for this control.

J. B. S. HALDANE.

Department of Biometry,
University College, London,
at Rothamsted Experimental Station,
Harpenden, Herts.

THE nine contributions to NATURE of September 6 on science and ethics seem to show by their extreme diversity how far thinking men may still be from an understanding of the scope and method of science.

Science is concerned with what a man (or a thing) must do, ethics with what he thinks he should do. Until the contrary is proved, therefore, we must suppose ethics to be derivable from science. How it is to be derived is a question on which scientific men cannot yet be expected to agree. But its historical relationship with the subject-matter of science, with the material conditions of society, is surely a commonplace. The one undergoes evolution, so does the other; and by evolution we mean the irreversible succession of changes which seem to be characteristic of all integrated systems. Take the Christian ethic. It has suffered three major recensions on its journey from the Sea of Galilee to the City of London, each of them well suited to the social and political conditions in which it has in fact proved fit to survive. Meanwhile other systems have arisen outside our own by revolution, and proceeded afterwards by an evolution faster than any we have known. As Prof. Julian Huxley has suggested, some of these systems may have sacrificed the credit of permanent adaptability for the cash of immediate advantage. That is a question which events are now deciding. In doing so these events have already displayed the somewhat Hobbesian principle which would be too obvious to repeat if it were not so often avoided, namely, that individuals will serve the State in proportion as they believe that the State will serve them. This is true at any given moment with little regard to whether that State's government is inherited, elected, or imposed, or all three together.

How the State is to serve the individual most efficiently will therefore depend, under rapidly changing conditions, on the adaptability even more of its ethical than of its political system; and our conditions are changing very rapidly. Evolution is no longer a hypothesis. It is happening on our doorstep. Now in all evolution there is a lag in the adaptation of one part of the organism to changes in another. The more extensive and more highly integrated the organism, the greater the lag. Our society is both extensive and highly integrated, and even the horrors of the industrial revolution in the North scarcely disturbed an ethical system emanating from the comfortable South. Now, however, the situation is different. We are faced, as before, with changing internal conditions. But our system is also in conflict with a second divergent system and at the same time in combination with a third, equally divergent.

It might be supposed that such a crisis is more likely to be resolved by empirical action than by analytical thought. That would be a mistake. Already during the present War political expediency has led to violent changes in the relations of the individual to society, changes which scientific method could have directed long ago and without any such compulsion. Why then should we not prepare for any worse emergencies by applying scientific method before they arise?

It may be objected that these questions for which a scientific solution is offered are not ethical but political. On the contrary, they are both ethical and political: the distinction lapses as soon as both are subjected to scientific treatment. What a man must do and what a man should do are always the same for the man himself at the moment he does it. In such measure as men submit to scientific discipline that sameness becomes extensible to the whole commonwealth. For universal agreement at successive levels of analysis is not merely the aim of science. It is an aim which experience shows has always been attained.

Science is therefore bound to be the foundation of the ethics of the future and of a system of ethics with some expectation of that universality which has hitherto failed mankind.

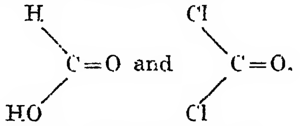
The Carbonyls

IN his recent Liversidge Lecture[1], Prof. Sidgwick has referred to the carbonyls as a "very peculiar group", but I would suggest that this is another problem which may well be approached through the medium of organic chemistry[2]. Thus we find that the capacity of a singly bound carbon atom for triple union with another atom does not extend beyond carbon and nitrogen to oxygen. Moreover, when carbon monoxide accordingly yields



the *two* new bonds are formed, in one case by acceptance, and in the other by a donation, of electrons on the part of the carbon atom. It must then be regarded as significant that those metals or ions which are actually able to participate in carbonyl formation are also usually, by reason of an incomplete inner electronic shell, equipped to fulfil this double function, and that in nickel carbonyl the nickel-carbon bonds are found to have a large amount of *double* bond character[3]. Further, it is presumably the result of the donor function of the central atom "that in nearly all the carbonyl compounds the effective atomic number of the central atom adds up to that of an inert gas"[4].

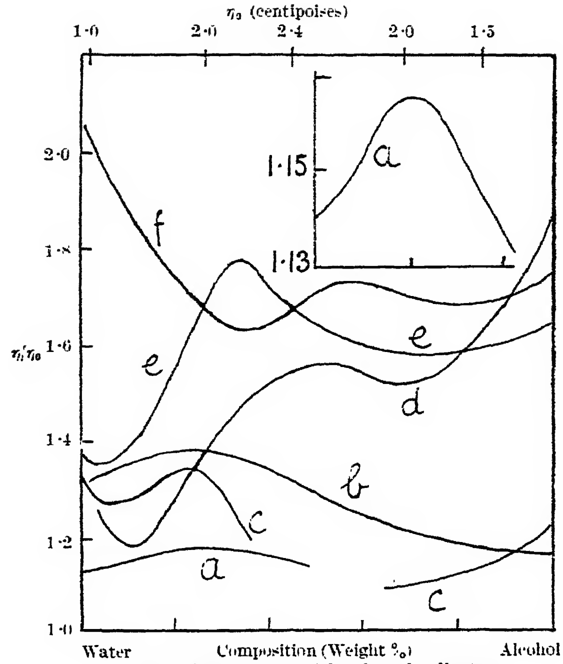
Viscosity of Suspensions and Solutions

IT was pointed out earlier[1] that the ratio η/η_0, where η is the viscosity of a suspension of finely divided solid particles in a liquid of viscosity η_0, is variable with η_0, being smaller for liquids of lower viscosity. The explanation in brief appears to be that during flow the solid particles become orientated more quickly in a thinner liquid, so causing less eddying by lying less across the stream of flow.

It is of interest to know that the same viscosity behaviour has been found both with solutions of colloids and crystalloids; if the above explanation holds good, then solvated ions are asymmetric, and during the flow of salt solutions and colloidal dispersions the particles become orientated.

When water and ethyl alcohol are mixed, there is an increase in viscosity reaching a maximum in the neighbourhood of 45 per cent by weight of ethyl alcohol, and it will be seen from the figure that the ratio η/η_0 for (*a*) sodium chloride, 10 gm./100 ml., (*b*) aluminium chloride[2], (*c*) potassium oleate[3], (*d*)



Insert shows curve *a* with enlarged ordinates.

tannic acid[4], (*e*) kaolin,[5] and (*f*) mica[5] dispersed in the binary mixture, increases with increase of η_0, the position of the maximum being affected by the dispersion changes.

Nomenclature of Pituitary Principles

I AGREE with Dr. F. W. Landgrebe[1] that the suffix *trophic* is inappropriate in application to all the known pituitary principles, but I cannot accept the argument that the hitherto accepted suffix *tropic* is unsatisfactory. It is true that τρέπω means *turn*, but the meanings *direct* or *change* also exist and provide a satisfactory basis for the use of the suffix *tropic* as descriptive of those pituitary principles which control or change other tissues or glands. The multiplication of names in a field in which the terminology is already plethoric is bound to lead to confusion, and I would urge that we retain the original suffix *tropic* as a general one to denote those pituitary substances which influence or change other tissues, irrespective of their mode of action. The growth of our knowledge of the nature and action of these substances will no doubt necessitate terminological reclassification, but perhaps in the future, as well as at the present time, the suffix *tropic* may be retained as a general one denoting those hypophyseal principles which influence, in a general manner, other glands and tissues.

PERSONALITY FACTORS AND PREFERENCE JUDGMENTS

By Dr. H. J. Eysenck,
University College, London

In a previous paper, certain correlations were reported between the temperamental characteristics of a number of observers and their scores on a test of æsthetic appreciation, the K test.[1] As these correlations were based on a comparatively small number of cases, and as the temperament test used was not quite in line with recent developments, the experiment was repeated with certain modifications.

Preference Test. The form of the K test used consisted of fifteen pairs of pictures (twelve pairs of landscapes, and three pairs of portraits) chosen in such a way that the two pictures forming each pair dealt with much the same subject, but in two diffierent ways. One treated the subject in the modern, colourful way associated with Cezanne, van Gogh and Modigliani, the other in the more academic manner of Hobbema, Constable and Wilson. The test is scored in terms of preference for the modern school.

Temperament Test. The Nebraska Personality Inventory was used in this investigation. This test was constructed by Guilford on the basis of his work on personality factors S, E and M[2]. For reasons which will become apparent later, it was decided not to use Guilford's scoring key, but rather to derive a scoring key from a re-analysis of the original correlations on which Guilford's personality factors are based. (I am very much indebted to Prof. Guilford for his kindness in sending me his original data and other material, without which such an analysis would not have been possible.)

Observers. The observers taking part were university students, W.E.A. students, and 'middle-class' people unconnected with academic life. Their ages ranged from seventeen to around fifty; sexes were distributed roughly equally. (I want to record my gratitude to Dr. P. E. Vernon, who very kindly gave the tests to a number of Scottish students.)

Results. Most modern workers seem to regard some such general dichotomy as introversion–extraversion as definitely established in the temperamental field. Guilford's analyses, which revealed no trace of such a general factor, were therefore received with some surprise. It would appear that the explanation of the absence of a general factor of this kind lies in the method of analysis he adopted; by using Thurstone's principle of rotation even a very strong general factor is invariably obliterated. In fact, the situation seems to be exactly parallel to that which prevails in the analysis of cognitive tests, where also the existence of a general factor is disputed by the adherents of Prof. Thurstone.

In the field of cognition it has been shown that the use of Prof. Burt's group-factor method makes it possible to arrive at a compromise between the claims of the 'general factorists' and the 'group factorists'[3]; this method enables us to assess quantitatively the relative importance of these various factors. It appeared reasonable to expect that an application of this method to the data collected by Guilford would lead to a similar compromise between those who claimed to have proved the existence of a general factor of introversion–extraversion, and those who favoured analysis into group-factors only. When an analysis by means of Burt's formula was carried out, a comparatively strong general factor appeared which accounted for 9·5 per cent of the variance and could easily be identified with introversion–extraversion; in addition, three group factors were extracted which accounted for 3·9, 6·4, and 3·5 per cent of the variance respectively. These group factors resembled closely Guilford's personality factors S, E and M.

(A similar result appeared when another research of Guilford's was re-analysed[4]. Here, because of a great deal of overlap, Burt's group-factor method did not seem applicable, and his general-factor method was used. A general introversion–extraversion factor was found to account for 14·8 per cent of the variance, while two other factors accounted for 8·7 per cent and 5·5 per cent respectively. The first of these factors opposed traits characteristic of *depression* and of what Guilford calls *rathymia*; the second factor opposed traits concerned with *thinking* and traits concerned with *feeling*.)

The correlation between the K test and extraversion, as tested by those items in the Nebraska Inventory for which scores could be derived from our analysis, was highly significant, being more than five times its probable error. For fifty observers it was $0·43 \pm 0·08$. This confirms the results reported earlier.

Only one of the correlations between the K test and the three group factors S, E, and M even approaches significance (according to Fisher's test of significance for small samples, a correlation of 0·27 would be significant). These correlations are: K and $S = -0·26$; K and $E = -0·05$; and K and $M = 0·08$.

The observers were asked whether they were conservative or radical politically; it was found that radicalism correlated with the K test to the extent of $0·34 \pm 0·08$, which is definitely significant, and also supports a previous finding[1].

One further point may be worth noting. Dr. P. E. Vernon, who had quite independently found evidence for a factor of the kind described earlier[1] found that those observers who had 'good taste' in painting tended to prefer the modern works, while the others tended to prefer the older artists. The observers in this experiment were asked if they were very much interested in art, interested in art, or not at all interested in art. The average scores of these three groups in the K test were respectively 8·8, 5·9, and 4·0, thus indicating that those who were very much interested in art tended to prefer modern art, and that lesser degrees of interest in art were accompanied by less liking for modern art. It cannot be maintained, of course, that those who say that they are very much interested in art are *eo ipso* those who have good taste, but so far as we can deduce anything at all from these results, they would seem to bear out Dr. Vernon's observation.

Conclusions. It has been confirmed that the K test correlates positively with extraversion and with radicalism. No significant correlations were found with personality factors S, E or M, although a negative correlation with S approached significance. Preference for modern art tended to be associated with general interest in art.

RADIO TECHNIQUE IN SURGERY

ALTERNATING currents of radio frequency, while used very largely for radio communication, broadcasting and navigation, also find extensive application nowadays in the hands of the physician and surgeon. Diathermy treatment by means of high-frequency currents has long been practised by the medical profession, but, more recently, other applications of radio technique have been developed. Two of these applications are referred to in considerable detail in the September issue of the *Wireless World*.

The first is described in an illustrated article by A. W. Lay entitled "Electrosurgery", and deals with the use of a high-frequency arc for surgical operations. In such an operation the high-frequency current passes between a specially shaped electrode held by the surgeon, and the patient, who is efficiently earthed by means of an electrode of large area applied in close contact to a smooth part of the body. The cutting effect depends upon the intense concentration of heat in a minute arc, which is struck and maintained at a point of the operating electrode during the course of the cutting stroke, which is controlled by the surgeon. An important feature of the use of this method is that raising the temperature of the blood to about 40° C. accelerates its coagulation and so checks bleeding. A high degree of skill is necessary on the part of the surgeon, as the active electrode must not be allowed to dwell at any point in the course of the cut; otherwise the resultant clotting is too deep, the tissue becomes charred and healing will not follow or will be seriously delayed. Should the electrode unavoidably sever a large blood-vessel, this may be closed by a pair of special forceps, through which a more intense current may then be passed to stop the bleeding.

The high-frequency energy required for cutting operations in general surgery varies from about 30 to 80 watts, and the critical cutting voltage is in the range 220–230 volts R.M.S. At voltages above 250 the arc is too fierce and then there is a tendency for the divided tissue to become charred, which, as already mentioned, must be avoided. Further research is needed to determine the exact process by which the heat disintegrates the molecular structure of the tissue; but if current of suitable value and character is applied, a very clean cut is obtained and the healing compares very well with the effects following the use of the surgeon's knife.

The second reference in the journal mentioned above, is a note referring to a communication in the *Lancet*, describing a radio-frequency probe for locating metallic particles, such as bullets and shell-splinters, in the human body, an instrument of obviously great utility at the present time. A low-power radio frequency oscillator has a tuning coil fitted into a sterilizable porcelain probe, 10 cm. long and 1 cm. diameter. If this coil approaches a metallic substance, such as a splinter, in the area of application, the inductance of the coil, and so the frequency of the oscillator, will change. This frequency change is detected audibly by means of a second reference oscillator, and a detector, amplifier and loud-speaker combination. The apparatus is in general equally sensitive to all metals, and can detect quite small particles, but naturally all metal instruments within a certain radius must be removed while the probe is in use.

The same application of radio frequency currents has been used previously for detecting nails in timber and for other similar purposes, where the location of metallic particles embedded in insulating material is required.

POSTGLACIAL UPLIFT AND THE MOBILITY OF THE EARTH'S INTERIOR

B. GUTENBERG of the Pasadena Seismological Observatory, California, has recently completed a study of the above problem ("Changes in Sea Level, Postglacial Uplift, and Mobility of the Earth's Interior", by Beno Gutenberg, *Bull. Geol. Soc. Amer.*, **52**, 721–72; May 1, 1941). The author has examined carefully the records of tide gauges throughout the world, and finds that these indicate that sea-level generally is rising at an average rate of about 10 cm. a century. In particular, maps have been constructed to show the rate of uplift in Fennoscandia and North America. A discussion of the new material and historic evidence appears to indicate that the uplift is a consequence of isostatic readjustment of the equilibrium disturbed by the postglacial melting of the ice. The remaining uplift is about 200 m. in Fennoscandia and possibly more in North America, where the present rate of uplift has its maximum of about 2 m. per century in the region of Hudson Bay. Simultaneously with the glaciation in Fennoscandia, the British Isles were covered by ice with a centre in the Hebrides where the postglacial uplift exceeded 30 m., decreasing towards Scotland; the zero isobase for the recent millennia intersects northern Ireland and northern England. There is some indication that the zero isobase at present lies south and west of Great Britain. Originally, the time needed to reduce the defect in mass to one half under the regions of uplift was less than 10,000 years, but it has been increasing with time and now exceeds 20,000 years.

Theoretical investigations on the plastic flow in the interior of the earth connected with the uplift have been critically discussed and extended by the author. According to Gutenberg, the movements affect the whole interior of the earth below the regions of uplift; their amplitudes decreasing slowly in the upper 1,000 km. If one assumes a strong lithosphere with a thickness of about 70 km., and below that the asthenosphere with a viscosity of the order of 10^{22} poises, and but little or no strength to prohibit plastic flow, there is no disagreement with observations related to isostasy or deep-focus earthquakes. Tectonic processes connected with isostatic anomalies larger than those in the regions of postglacial uplift are judged to be connected with plastic flow at least down to the core. Gutenberg suggests that defects of mass producing only relatively small gravity

anomalies are able to produce plastic flow if sufficient time is available. The lower limit, below which the processes stop, is important. The *Polfluchtkraft* probably produces stresses of the order of one hundredth of the stresses in Scandinavia stated to be large enough to maintain plastic flow. If the *Polfluchtkraft* is large enough to maintain plastic flow, then we should not be surprised to see continents being shifted by subcrustal flow during the history of the earth under the action of such small *but persistent* forces.

RESEARCH IN GEOPHYSICS

THE annual report of the director of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, published in December 1940, is an important record of achievement carried out under difficulties caused by war. It describes the initiation of several fresh experimental projects, the continuance of the previous programme of field observations, the reduction of existing data, the organization of and participation in several important congresses, and the publication of a large number of scientific papers.

With the aid of a cascade high-pressure bomb, hydrostatic pressures in excess of 200,000 atmospheres were attained at the Geophysical Laboratory. This apparatus renders possible the investigation of the magnetic properties of materials at pressures comparable with those actually existing in the earth's interior. For a specimen of cadmium-magnesium-iron-spinel under a pressure of 10,000 atmospheres, a shift in the Curie temperature of as much as 5° C. was observed. These measurements necessitated the development of an alternating-current bridge capable of responding to changes in inductance as small as $1/10^{10}$ henry.

One of the outstanding problems in atmospheric electricity arises in connexion with the 'supply current', which in an undetermined manner supplies negative electricity to the earth at a rate of about 1,800 amperes, and so maintains a negative charge on the surface in fair-weather areas. The actual current flowing from air to earth in such areas depends to some extent upon meteorological and other more or less local factors, which have to be taken into account in arriving at a measure of the supply current.

In connexion with the volcanological investigations planned by the Institution, a series of earth resistivity measurements were carried out with the view of determining the thickness of the extensive deposits of volcanic ash occurring in Guatemala. Depths extending to 600 miles were recorded.

Laboratory work in nuclear physics centred around the high-voltage electrostatic generator, which was induced to yield tensions up to 3–6 million volts, and the installation of a 60-in. cyclotron. Measurements were made on the scattering of slow and fast neutrons by collisions with protons, on the resonance scattering of protons by helium nuclei, and on the splitting of the deuterium nucleus into a proton and a neutron by high-energy gamma radiation.

It is proposed to employ the cyclotron, when completed, in connexion with work of a biological and chemical character, utilizing the radioactive isotopes of ordinary elements as tracers for following various reactions. A scheme for the adequate shielding of those operating the cyclotron from the powerful radiations generated by it has been worked out.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

FRIDAY, SEPTEMBER 26

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 2 p.m. —Joint Discussion with the Library Association and the Association of Special Libraries and Information Bureaux on "The Preparation of Indexes to Volumes of Periodicals" (Opener: Dr. S. C. Bradford), and "Listing Titles of Periodical Publications" (Opener: Mr. E. Lancaster-Jones).

FRIDAY–SUNDAY, SEPTEMBER 26–28

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at the Royal Institution, Albemarle Street, London, W.1).—Discussion on "Science and World Order".*

FRIDAY, SEPTEMBER 26

Morning Session: "Science in Government" (Chairman: Sir Richard Gregory, Bart., F.R.S.). Afternoon Session: "Science and Human Needs" (Chairman: Hon. J. G. Winant).

SATURDAY, SEPTEMBER 27

Morning Session: "Science and World Planning" (Chairman: Mr. I. M. Maisky). Afternoon Session: "Science and Technological Advance" (Chairman: Dr. E. Benes).

SUNDAY, SEPTEMBER 28

Morning Session: "Science and Post-War Relief" (Chairman: Dr. Wellington Koo). Afternoon Session: "Science and the World Mind" (Chairman: Mr. H. G. Wells).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN PHARMACEUTICAL SUBJECTS, and a DEMONSTRATOR IN PHARMACEUTICS—The Principal, College of Technology and Commerce, Leicester (September 27).

ASSISTANT LECTURER IN PHARMACEUTICAL CHEMISTRY—The Registrar, University College, Nottingham (September 29).

LECTURER IN ELECTRICAL ENGINEERING AND ALLIED SUBJECTS—The Principal, County Technical College, Worksop, Notts. (September 30).

SENIOR LECTURER (MALE) IN EDUCATION—The Principal, Training College for Teachers, Collegiate Crescent, Sheffield (September 30).

CHIEF INSTRUCTOR with experience as Head of Engineering Branch of Technical Education, a SPECIALIST IN PHYSICS, and TWO SENIOR and TWO JUNIOR LECTURERS who should be Physicists or Specialists in Mechanical Engineering, for the training of Ordnance Mechanical Engineers in India—The Secretary, Military Department, India Office, London, S.W.1 (October 1).

HEADMASTER of Stockport Grammar School—The Clerk to the Governors, Stockport Grammar School, Mile End, Stockport (October 15).

LECTURER IN ENGINEERING SUBJECTS in the Rotherham College of Technology and Art—The Director of Education, Education Offices, Rotherham.

EDUCATION FOR INTERNATIONAL RECONSTRUCTION

THE present phase of the War seems particularly appropriate for further consideration of the possibilities arising out of the unrest which is growing in the countries of Europe at present under Nazi control. Propaganda is obviously of high importance in this connexion, and the announcement that the Government has appointed a directorate of political warfare to co-ordinate the whole of our foreign propaganda indicates awareness of the urgency of the situation ; the board will include representatives of the Foreign Office, Ministries of Economic Warfare and Information, and the British Council, and the B.B.C. and other bodies will co-operate. Three recent publications referred to below* make valuable contributions to the discussion of the subject.

Prof. Keeton attributes the failure of the attempt at world organization through the League of Nations to the absence of an international public opinion, and points out that to establish the machinery for international organization without such a public opinion would be to court failure a second time. International public opinion, however, does not grow of its own volition. It is primarily an educational process, and it is as a contribution to the formation of such an opinion that Prof. Keeton urges the formation of an international university.

The creation of an international solidarity sufficiently powerful to make international institutions an effective reality involves the use or development of an adequate technique, the abandonment of the indifference to the needs of human association which has been so common in democratic communities in recent years, and the establishment of some forum for the discussion and exposition of the methods to be used in establishing an international order. Developments such as the 'Round Table' discussions of the University of Chicago need to be taken up in Great Britain and widely extended, and an international university would have as one of its main tasks the organization of research into all those problems which arise in the achievement of a world order, and the publication of the results of such investigations.

An even greater task than research would be the teaching, both of the adult communities and of the youth, of those nations which supported the project. This is a task calling for much imagination and creative thinking as well as for careful organization, if we are to avoid the mistakes that have

Offensive against Germany. By Sebastian Swaffner. (Searchlight Books, No. 2.) Pp. 128. (London: Secker and Warburg, 1941.) 2*s*. net.
P E P Broadsheet: The Future of Germany. (London: P E P, 1941.)

devitalized the adult education movement in Great Britain, and to foster the development, not of a hybrid internationalism, but of an ordered nationalism, seeking to establish the place of individual national cultures within the general pattern. Some of the work which has already been carried out in this field by the Committee of Intellectual Co-operation of the League of Nations has pointed the way, and the beginnings of an interchange of students and teachers already existed before the War.

What is now required is that these possibilities should be explored, not in an academic spirit, but with vigour and vision in full realization of the contribution they offer to the very founding of a new order. For that reason this task cannot be dismissed entirely until hostilities cease. The opportunities that lie to our hand must be seized and used as part of a great moral and spiritual offensive.

Although in his earlier book Sebastian Swaffner directed attention to the offensive value of an international academy, which could so easily be established in Great Britain now that there are so many *émigré* scholars in our midst, apart from a reference in Mr. Eden's speech of July 6 there have been few indications that the significance of the existence in London of a miniature Europe is realized. It would indeed be short-sighted policy if, in the recruitment of their services in our war effort, we overlooked these larger possibilities and failed to utilize their learning and skill in a direction which would demonstrate at once the shallowness of the Nazi pretence of a united Germany or Europe, and make so important a contribution to the preparation of a new European order.

In his "Offensive Against Germany", Swaffner says little about his earlier proposal for such an international academy or university. He is concerned primarily with what he terms the moral-psychological strategy of the War, of which so far we have allowed the Nazis the monopoly. Our attention to morale has been largely the defensive one of maintaining that of our own people, rather than the offensive one of breaking down the morale of our enemy. It is Swaffner's analysis of the weaknesses and vulnerability of German morale, of the methods and prospects of attack rather than his own plan of attack, that give value to his book. It is directly complementary to the P E P broadsheet, for the strategy of political warfare as well as the tactics used to attack the enemy's morale must be largely influenced by our view of what solutions of the problem of Germany are possible.

The P E P broadsheet starts with an analysis of the salient features in the current German situation, pointing out that the concentrated drive of the earlier phase of Nazism is becoming dissipated as an inevitable result of the extension of the Nazi campaign from a limited field where the Germans are in a majority to the wider European field in which they are outnumbered by at least four to one. Simultaneously, the clear-cut ideology and sense of mission developed in a closed artificial atmosphere is becoming confused or even inhibited, while the aggressive spirit of indicting an indefensible old order is giving place to a defensive attitude towards an even less defensible New Order. Strategically, these developments have led to immensely extended and increasingly costly and vulnerable lines of communication. Politically, they involve the inclusion within the German system of a majority of inhabitants non-German in sympathy and increasingly anti-Nazi in attitude. The need for absorbing and restarting a vast range of industries built up in competition with German industry throws a strain on the economic system comparable with that which in the administrative sphere has involved a sacrifice of much of the homogeneity and efficiency achieved by the Nazi system.

No violent revolutionary movement within Germany is to be looked for before or even after a military defeat, but the chances are strongly against successful Nazification of the territories occupied by Germany during the last eighteen months. The chances, on the contrary, are strongly in favour of growing spontaneous resistance movements in neighbouring occupied or threatened territories contributing to German defeats through sabotage, passive resistance and ideological means. The broadsheet concludes that development of these movements, rather than any development within Germany, is likely to shape the future social pattern of a defeated Germany, which must draw heavily from outside to replace the shattered influences now temporarily superseded by Nazism.

Visualizing the immediate post-war period, the P E P broadsheet suggests that there should be four stages in Germany as a whole or in any part of it. First the termination of Nazi power either by driving out the armed forces and Gestapo or by their surrender and demobilization. Then come the establishment of emergency military administration by occupying forces, and the prompt creation of as strong a bulwark against disorders and the lawless seizures of territory as conditions may require. The transfer of all civil affairs to a Reconstruction Commission, including American and of other independent members, as well as political, economic and medical branches, follows, and finally the gradual development of appropriate German self-governing bodies and the gradual transfer of power to them.

Disintegration of a defeated Germany is likely to be much more complete in the present war than

in 1918, owing to the destruction of alternative nuclei and to other factors, but there is no reason why we should not let this disintegration run its course. The bulwark for the protection of Europe as a whole should be formed at first exclusively of non-German forces, and the military occupation of Germany is essential as the first stage in a carefully planned and directed re-creation of German institutions as an essential part of European reconstruction. Successful post-war treatment of Germany depends on the reconciliation of two apparently contradictory propositions: the German people can never again be trusted not to abuse their strength by trying to trample on weaker neighbours, and any settlement which discriminates against and refuses to trust the German people contains the seeds of another German war.

The P E P broadsheet concludes accordingly that Europe must be organized so as to divorce national structures from military and industrial power. This organization must be backed by world control of raw materials and communications, with the object not only of facilitating economic expansion, but also of thwarting policies of autarchy and militarism by automatic sanctions. The post-war settlement of Europe should be along the lines of the British Commonwealth rather than a written constitution, and within this framework the extent of a future German State should be decided by the unfettered choice of the peoples to be included in it. Establishment of social and economic opportunity and security is the only practical basis of enduring peace, and the winning of the peace depends on Britain holding the initiative and using it in the long-term interests of the European majority, and in the convergent interests of the United States and the Dominions, whose co-operation would be needed at every point. Behind this policy there must be visible British sea- and air-power, backed by war industries, maintaining stores instantly available to threatened countries on lease-lend principles, and by availability of strategic bases.

It is against this background that the value of the meeting between President Roosevelt and Mr. Churchill and the Charter of the Atlantic which issued from it must be assessed. The manner in which the eight points of the Charter meet the conclusions drawn from the P E P analysis of the German problem justifies the view that the Charter is a political weapon of the first order. The whole circumstances in which the meeting was held dealt such blows to German claims and propaganda that it can well be hailed as the launching of the moral and political offensive for which an important section of opinion in Great Britain has been pressing. If these hopes and expectations are justified, and the Government seizes the opportunities now opening in this field, and by the effort and thought which it devotes, not sporadically but continuously and systematically, to political warfare, we may well find in this meeting and Charter the token that the path to the New Order for which we strive may be shorter and less tortuous than anything which the military, naval or air situation would warrant our believing.

MAN AS A SOCIAL ORGANISM

Human Nature and the Social Order
By E. L. Thorndike. Pp. xx+1020. (New York: The Macmillan Company, 1940.) 18*s*. net.

"WHAT can men do, what do they do, and what do they want to do?"—these are the questions that Prof. Thorndike seeks to answer in a very comprehensive and elaborate treatise. His undertaking is inspired by the belief that man has the possibility of almost complete control of his fate if only he will be guided by science, and that his failures are attributable to ignorance or folly. The main approach is through biological psychology, but all the social sciences are appealed to and utilized in an effort to deal with the human problem as a whole. The relative immaturity of the sciences dealing with man is continually stressed, but it is claimed that they provide a body of facts and principles which are "far above zero knowledge", and that even now they are capable of affording valuable guidance in the shaping of public policy.

The picture that Prof. Thorndike draws of human nature and its possibilities is based on a view of mind reached by him in his well-known and extensive studies of animal and human behaviour. Man is depicted as a bundle of inborn capacities and wants which are gradually organized by the action of the environment. The underlying conception is on the whole mechanistic. Man is a network of connexions between stimuli and responses operating in the service of a group of wants. A structure is built up as the result of the strengthening of connexions through repetition and the experience of satisfaction and annoyance. It is assumed that for every variation in response

there is traceable a variation in the pre-formed structure. The fact that purposes operate is not denied, but this is not held to be incompatible with the postulates of mechanistic science. Purposive action, Thorndike thinks, is action determined by the consequences of the act. But such determination by consequences is made possible by the fact that whenever a goal is reached after striving there is an experience of satisfaction, and this sets up a 'confirming reaction' which has the property of strengthening any modifiable connexion on which it acts.

The account which is given of human capacities makes use of the vast amount of work which has been done on individual differences. In dealing with abilities stress is laid on their specific character. Factorial analysis is not, in Thorndike's view, likely to reveal the ultimate mental elements, but only statistical composites of them. It would seem that the mind must be conceived as an undifferentiated aggregate of innumerable elements, a mass of imperfectly correlated powers. A like insistence on variety, complexity and specificity is to be noted in the account given of human wants. Thorndike will have nothing to do with those who have tried to reduce the wants of mankind to some small number of primary desires, such as for love, security and power.

The wants of man are innumerable, and to discover how far they are rooted in inborn need, and how far they are artificially generated is a matter of the greatest difficulty. Yet he does give a list of primary desires and aversions, and quotes estimates made by juries of psychologists and others of the time and money spent by adults in the United States in satisfying these desires. Thus judged, it appears that about a fourth of the waking hours are devoted to the needs of subsistence and perpetuation, about a third to entertainment, about a tenth to companionship and affection, and an equal amount for the approval of self and others. Only four per cent of the working hours are given to intellectual wants, and about eight per cent to the welfare of others. Security claims only about seven per cent. As judged by the amount of money spent, it would appear that less than a third of the expenditure is allotted to keeping the population alive and able to reproduce itself; the pleasures of the senses take a tenth, the pleasures of the intellect less than half that. The selfish satisfactions take more than a fifth, and more than a third if the satisfactions of love and benevolence are included. The desire for security takes a tenth.

The value of these estimates which are here quoted as an example of the numerous investigations cited in the work will be doubted by many. Apart from the difficulty of classifying the concrete activities of daily life under broad headings like security, benevolence, and the like, the estimate seems to ignore the distinction between things that need to be bought for money and things that money cannot buy. Nevertheless, the case that Prof. Thorndike makes for the assumption that behaviour runs parallel with, and reveals the strength of, desires and aversions is impressive, and his hope that ultimately reliable scales of measurement will be discovered and effectively utilized in the social sciences may be well warranted.

Prof. Thorndike recognizes that in dealing with social policy we need to know not only what men's capacities are and what they actually want, but also what they ought to want and to avoid. The search for a standard of values is, indeed, regarded by him as "the most important job for thinking men" at the present time. He has, however, little faith in philosophical ethics, and makes a powerful plea for a natural science of values. By this he understands a study of the bearing of acts and conditions on the satisfaction of wants, present and future. Its task would be to give an exact enumeration of wants, of the varying weights to be attached to their satisfaction, and an estimate of the probable consequences of acts in the way of satisfaction or annoyance. He realizes, of course, that we cannot simply identify goodness with the satisfaction of wants, since we often disapprove of what we want. Nevertheless, he thinks that all moral and prudential judgments are ultimately "justified by wants". Presumably we should have to distinguish between wise and unwise wants, but it is difficult to gather what constitutes wisdom and the lack of it in this context. If maximum or harmonious satisfaction is the criterion, we must ask whether this is justified on the ground that people actually want such satisfaction or on the ground that they *ought to* want it, and if, with Prof. Thorndike, we lay stress on justice and impartiality in the allocation of satisfactions, is our ground for doing so to be found that men in fact want justice or impartiality or that they ought to want it.

The problem of the relation between what is desired and what ought to be desired is not seriously faced. I suggest that though a natural science of values is both possible and important, such a science will not of itself solve the problems with which philosophical ethics is concerned, and that judgments of value differ from judgments of fact more radically than Prof. Thorndike would allow. It remains that his careful enumeration of the elements of human welfare would probably find a large measure of agreement in democratic societies, and that an examination of social and political institutions in the light of criteria deducible from them would afford valuable guidance in the task of reconstruction. Of special interest is

the account given of the methods that can be used for comparing the welfare of different communities by means of a weighted average score of their status in matters of health, education, recreation and social well-being.

To the application of his fundamental principles Prof. Thorndike devotes the major part of his treatise. He deals in turn with the problems of the family and eugenics, property and economic organization, law and government. In general his recommendations are in harmony with what might perhaps be called liberal individualism, though he is not so anxious to restrict the sphere of governmental activity as some individualists, and throughout he lays less stress on the particular conclusions he reaches than on the importance of scientific guidance and research in all matters of social policy. Somewhat strange is his treatment of the principle of equality. This he interprets literally, forgetting that most defenders of the principle do not mean by it the view that all should be treated alike, but rather that all differences in treatment require justification in terms of differential merit or need. In this sense of proportionate equality, justice cannot be contrasted with equality, but is, as Aristotle showed, based on it. Indeed, the principle of proportionate equality is implicit in Prof. Thorndike's own discussions.

These matters cannot here be further pursued. Something must be said, however, on the adequacy of the general theory of human nature and society which is here adopted as the basis of inquiry. We must ask, to begin with, whether a theory of society can be built up on the basis of a psychology of individual differences. Prof. Thorndike seems to think that the differences between communities resolve themselves ultimately into differences in endowment of the individuals composing them or in the range of distribution. But social structure can scarcely be interpreted in these terms. The social classes within a community, for example, are not in the main determined by differences in individual endowment, and changes from one type of social stratification to another have nothing to do with changes in genetic endowment. Similarly, on the basis of very similar genetic endowment very different social institutions can be built up. A science of society must therefore be largely a study of social forces, that is, of the forces which arise out of the relations between human beings. No amount of knowledge of individual differences will help us to determine the changes that are likely to be produced in a society by a change in the structure of the family or the penal law. Psychology cannot do the work of sociology. The direct study of social change is especially important if a basis is ever to be found for the calculation of the consequences of acts which Prof. Thorndike insists is so important in dealing with values. His approach here seems to me too individualistic, just as his conception of the human mind is too atomistic. Similarly, in his discussion of valuation, he never raises the question which now, above all, confronts all societies, of the relation between the good of individuals and the good of society. No doubt the elements of human welfare which he enumerates inhere in individuals, but may there not also be value in the forms of social life, for example, in certain types of family life or types of community ?

Finally, Prof. Thorndike's account of the nature and role of purpose in human life raises doubts. If purposive behaviour is but a back-stroke of past experience, a reaction confirmed by past experiences of satisfaction and annoyance, we should expect past experience to be far more effective in the shaping of human purposes than in fact it appears to be. Neither the folly nor the grandeur of human endeavour is in keeping with such dominance of the past. Both imply a power of reference to the future which goes beyond the past, and is in a real sense directive and forward moving, whether for good or ill. MORRIS GINSBERG.

Town and Country Planning

A Study of Physical Environment ; the Prelude to Post-War Reconstruction. By Gilbert McAllister and Elizabeth Glen McAllister. Pp. xxxii+176+12 plates. (London: Faber and Faber, Ltd., 1941.) 12*s*. 6*d*. net.

THERE has been a great deal of talk of reconstruction since the German bombers have done so much damage to British towns : the five years plan for slum clearance which had been embarked upon before the War, the tentative efforts at central re-planning (of which the Bressey Report for London was an example), the recommendations of the Royal Commission on the Location of Industry—these and other similar projects were given a sudden possibility of rapid realization, through the barbarous results of destruction. Instead of the cautious, considerate, hesitating way in which we have so far attempted the reform of our environment, giving way to private interest, fearing to incur expense, lacking

in faith and vision, something now will have to be done, and done rapidly, the moment the War ceases and national effort turns to the needs of peace. New houses, new roads, new factories must be constructed—the dilatory method of a five-year plan which takes twenty-five to accomplish, will no longer serve: either these buildings and means of communication will be huddled up or laid down on their old sites, perpetuating the old conditions (with slight tactical improvements) and leading to the old problems of wasteful existence, or the opportunity will be seized and some good at least be created to make up for the monstrous loss through the War.

It is to prepare the way for a full use of this opportunity that Mr. and Mrs. McAllister have written their prelude to post-war reconstruction: they do not, as yet, attempt to plan, but provide us with the background upon which planning should be based; in this same series and also under the ægis of the Town and Country Planning Association, a future volume by Mr. F. J. Osborn will forecast the lines upon which planning, to fulfil its function of providing an environment, healthy, convenient and beautiful, should proceed. The McAllisters' task is the very necessary and preliminary one of setting forth the magnitude of the work against a historic background, showing how the standards which we must aim at are part of a process of evolution which is continually advancing.

I have mentioned three of the main objectives of planning—housing, industrial location and transport; to these should be added agriculture (which requires special treatment as compared with most other forms of industry) and recreational open spaces (both inside the town and outside). This book is more particularly concerned with the housing aspect: as the authors say—". . . informed opinion, the technical town-planners . . . and perhaps most of all those who approach town-planning not as experts but as sociologists, interested in humanity and anxious for that progress which good environment can achieve, must begin . . . by a consideration of *the needs of the family*". They have accordingly dwelt upon the standards of design, space and density required for the good family life. They recapitulate, familiar though the figures may be, the bad effects upon health of unsatisfactory home conditions and especially they insist upon the advantage of the house in its garden as compared with the dwelling in its tenement block. But they point out clearly the dilemma which the continued growth of the great towns forces upon the home-seeker: "either suburbia and a garden and a tedious daily journey or flat life and no garden and an environment unsuited to family life". On the other hand they show how necessary it is to integrate the different aspects of community life. Readers of NATURE are familiar with the biological triad, environment, function and organism, translated by Patrick Geddes into place, folk, work. The authors show that a dormitory housing estate "divorced from industry" is insufficient; that a trading estate is an "atrophied, unbalanced development" without provision for residence. They then build up this admirable picture of all-round development: "Put a Trading Estate and a good housing estate together and you have roughly two-thirds of a town. Add to them facilities for shopping, for social life, for education, for entertainment, and you have four-fifths of a town. Limit the size of the town by encircling it with a belt of country, devoted exclusively to agriculture and to recreation and prohibit all building development within the belt, and you have a town that satisfies human needs. . . ."

This could scarcely have been better put and we can therefore forgive them if 142 pages out of 168 are given to housing, as this is the authors' special subject, and they have made it abundantly clear that they realize, and make the reader realize, the position of housing in the urban complex. The last two chapters, indeed, are a useful summary of planning powers and needs, both local, regional and national. They give a brief description of the position of statutory town-planning at the outbreak of the War and direct attention to its predominantly permissive character as compared with the positive constructive planning now required, not only to make good the destruction from bombing but also to provide for a proper location of houses and industry when the general dislocation which obtains to-day is to be reintegrated.

The main body of the book covers the many aspects of housing, including two useful chapters on building costs and organization of the building industry. It will be remembered that high building costs broke the Addison Housing Scheme after the War of 1914–18, and it is to be hoped that drastic steps will be taken to prevent a recurrence; after this War the rush for building will be much more intense, so that the capacity of the industry to cope with it is of vital importance. Costs and capacity to build are closely interrelated.

From the above brief summary of this closely packed volume of information, it may be judged how useful it should prove both to the general public which should be fully informed, as well as to official bodies, both local and governmental, which, of course, have the information, but sometimes can learn from an unofficial presentation of the facts.

PATRICK ABERCROMBIE.

COMPUTATIONS IN NAVIGATION

Marine Navigation
By Lt.-Comdr. P. V. H. Weems. Pp. x+443. (London: Chapman and Hall, Ltd., 1941.) 30s. net.

WHILE we may applaud Lieutenant-Commander Weems's efforts to simplify, to shorten and even to obviate the computations incidental to navigation, we cannot but regret his verbosity and his lack of lucidity. It is difficult to see for whom his book has been written. It would confuse and might well mislead a beginner. It will prove tiresome to an old hand trying to bring himself up to date, who will have to refer to the index and turn up several pages before he can arrive at a complete account of the new method and an example worked by it. A case in point is that of star altitude curves. A sample page showing some of the curves is given on p. 334, directions for use and some sort of explanation on pp. 353–57 and a worked example on p. 367.

Many of the diagrams are clear and self-explanatory; others are cluttered up with lettering. Many of the illustrations are too dark, or on too small a scale: others are redundant.

There is, however, much that is of interest. In Chapter 3 we are introduced to a set of five blank charts, WSN charts, devised by three cartographers at the author's request. We gather that they are adaptations of Lambert's conformal projection and that they preserve angles and represent great circles by straight lines with sufficient accuracy for the purposes of navigation. The distance and the initial and final courses on each of four great circle tracks have been taken from these charts and compared with those found by full-dress solutions of the spherical triangles. The differences are all insignificant. We may take it, then, that these WSN charts are as quick and handy for great circles as those of Mercator for rhumb lines. We may also accept the author's method of determining the directions of rhumb line chords of a great circle. But WSN charts are blank and "A sensible navigator would never compute and sail a course without referring it to a regional chart" (p. 110), that is, in effect, to a Mercator's chart.

In Chapter 10, on radio navigation, we hoped to find the latest methods of laying down a position line obtained from a wireless bearing. The position line is not mentioned: we are told to convert the great circle bearing to the mercatorial bearing and to plot the rhumb line. Curves of equal (constant) bearing are only mentioned in the title of a picture of a chart of the North Atlantic on which two families of them have been drawn. But one cannot talk away the fact that when the difference between the great circle and mercatorial bearings is significant, so also is the angle between the curve of constant bearing and either of the other two curves.

The chapters on celestial navigation are more satisfying. The rudiments of nautical astronomy are clearly and simply explained in a way that should help a beginner. Those that deal with the latest forms of almanacs are of interest. Lieutenant-Commander Weems has personally instigated and contributed to innovations that have reduced both the time and labour of working a sight.

Of the computations that a navigator cannot avoid when translating observed time and altitude into a position line the longest is the solution of the spherical triangle determined by a local hour angle (L.H.A.) and the declination of the body observed and an assumed latitude. With an almanac of the older pattern the computation of L.H.A. involved the determination and the application of the error of the watch on G.M.T.; the extraction of two elements (one only for the sun) from the almanac, entailing interpolation; the application of these and an assumed longitude to the observed time. The use of second setting watches and frequent time signals obviates the first step. An account of these watches and also of sidereal watches is given in Chapter 17. The U.S. Nautical Almanac and the British Air Almanac now tabulate the Greenwich hour angle and provide appropriate tables to reduce it to L.H.A. by interpolation, thereby shortening the remaining steps.

For the solution of the triangle, more than one set of tables has for long provided the answer by inspection and interpolation. All of them are voluminous, and but few navigators appear to use them. The tables of the Brazilian Aquino, for solution by division into two right-angled triangles, are handy and quick. They deserve more attention than they have received. At this stage we would join our author (p. 335) in impressing on navigators that much interpolation is saved without significant loss of accuracy by suitable selection of the assumed latitude and longitude. The tables published by Lieut.-Commander Weems are for the same solution as those of Aquino and appear in his "Line of Position Book", sample pages of which are included on pp. 342, 343. They are quick, easy to use and, so far as we can tell,

sufficiently accurate. On pp. 362–65 a sight is worked by them and also by other similar tables for purposes of comparison. To judge by the number of figures used, Lieut.-Commander Weems's "Tables" and Hughes's "Sea and Air Navigation Tables", which appear to be identical, win in a dead heat.

The star altitude curves, referred to in the first paragraph of this note, are curves of equal altitude of certain selected stars, numbered to allow for refraction and plotted on a Mercator's chart. Their object is to provide a very quick means of obtaining a complete fix. The directions for use are explicit enough and that use is not limited to the selected stars. The explanation of their why and wherefore would puzzle a beginner. We have not tried them out.

G. V. RAYMENT.

PSYCHOLOGY FOR STUDENTS

A Biological Introduction to Psychology
An Introduction to Psychology for Students and Practitioners of Medicine. By Prof. R. J. S. McDowall. Pp. xiv+210. (London: John Murray, 1941.) 6s. net.

THERE are innumerable introductions to psychology, but few claim the distinction of being "biological" introductions. One therefore turned to this book, which was written by the professor of physiology at King's College, in the expectation that it would be something unusual. It might have been expected, for example, that it would have been written on evolutionary lines or along the developmental levels of the nervous system, since biology is mainly a study of increasing complexity in animal life. It might have progressed from the simple reflex to the greater complication of chained reflexes and thence to the instinct, the control of instinctual urges and the emergence of consciousness, the properties of memory, forgetting, and finally with the abnormalities associated with deranged function, so as to make a coherent whole.

Unfortunately, Prof. McDowall has not chosen a biological plan but has made an effort to make his book all-inclusive and so introduced unnecessary complication. He commences with a short section on adaptation. He then considers conscious activity, but follows this with processes of the nervous system. He proceeds to life's motives and the instincts. This section on the instincts includes the security instinct, the sex instinct, the power urge, and the spiritual urge. (It will be seen from this that Prof. McDowall does not adhere to the usual conception of the instincts, but adopts Adlerian theories and, in the spiritual urge, views which would be unacceptable to a large number of psychologists.) The last section of the book includes personality, reasoning, suggestion and hypnosis, dreams, the effects of mental states on bodily reactions, and the evolution of the individual.

There are a certain number of mistakes which are regrettable. For example, on p. 48, the author says "These phobias, or 'fixations' as they are sometimes called," and again on p. 49 he states "Many (i.e. phobias) are so deep, so fixed and so difficult to eradicate that in psychological parlance they are known as 'fixations.'" Such statements seem to show that Prof. McDowall does not appreciate that a fixation is a special term concerning emotional development in relation to the causation of neurosis or psychosis.

It would be unfair to condemn this book for such mistakes. It is a reasonably good introduction for the student as long as he is prepared to find it merely an introduction to psychology without having any special merit by being "biological". Moreover, it will please many by being essentially of the common-sense type, avoiding undue adherence to any particular school of psychological thought and making any assertions which need other than a superficial knowledge of psychology to appreciate. The style of the book is pleasant and friendly, and obviously inclined to lead the student gradually on from section to section.

There is a short appendix, which contains a number of case notes taken from Ross's "The Common Neuroses", Henderson and Gillespie's "Text-book of Psychiatry" and Howe's "Motives and Mechanisms of the Mind", etc. It is a merit of the book that it is not padded out with case notes, and those who write psychological books are well advised to follow Prof. McDowall's plan of placing case notes in a separate section so that they can be read apart from the text. The index is good and quite sufficient for a book of this kind. It would have been a good plan if a wide bibliography had been added, however, since an introduction of this kind should lead the student on to wider and more comprehensive reading. This would allow him to fill in the superficialities inevitable in an introduction and to correct the mistakes which have slipped into the text.

THE RISE OF SCIENCE IN RUSSIA

By ENG.-CAPTAIN EDGAR C. SMITH, O.B.E., R.N.

IN 1698, on February 6 and again on March 8, Peter the Great visited Greenwich Observatory, and as Flamsteed recorded, made observations of Venus. In Holland he had studied astronomy and other sciences, he had inspected Leeuwenhoek's microscopes and Ruysch's anatomical collections, and thus while pursuing his main object of learning shipbuilding and recruiting instructors and artisans, both in Holland and England he made himself acquainted with some of the science of the day. He was then about twenty-six years of age. Twenty years later he again visited Holland, but this time went on to Paris where he inspected the Arsenal, tapestry and printing works and natural history collections, went to the Sorbonne and Observatory and attended a meeting of the Royal Academy of Sciences, where he talked of maps. The newly founded city of St. Petersburg had already become his seat of government, in preference to Moscow, and one of his cherished ambitions was to establish in it an academy after the fashion of the Paris and Berlin Academies of Sciences and the Royal Society of London.

This scheme, however, Peter did not live to carry through, and it fell to his widow and successor, Catherine I, to inaugurate the Imperial Academy of Sciences, which for two hundred years was the scientific centre of the Russian Empire. The Academy was established in 1725, and it was at the last ordinary meeting of the Royal Society presided over by Newton that a letter from the Academy was read giving an account of its inauguration. Though the City and the Academy have changed their names (and the latter its location) they both are monuments to Peter the Great, who was the first to open the hitherto closed portals of his Empire to scientific thought and knowledge.

It is perhaps unnecessary to dwell on the backward state of Russia in the seventeenth century. Though the Empire stretched from the Baltic to the Pacific, from the Arctic to the Caspian, there were few schools and no universities. Russia can lay no claim to a Copernicus, Kepler or Galileo; and the older histories of science can be searched in vain for the names of Russian contributors to natural knowledge. When the Academy of Sciences was in the making it was therefore necessary to draw its members from other lands, and so from France came its first astronomers, from Switzerland its first mathematicians and from Germany its first naturalists, and right throughout the eighteenth century, not only men of science, but also others learned in history, languages or architecture or skilled in painting, mechanics or engineering, were recruited from western countries by succeeding sovereigns. All these men were made members of the Academy of Sciences, provided with comfortable homes and adequate pensions, and St. Petersburg was the main centre of their activities.

Among the earliest to arrive in St. Petersburg were the French astronomer Joseph Delisle (1688–1768) and his brother Louis Delisle de la Croyère, and the Swiss mathematicians, Nicolas Bernoulli (1695–1726), his famous brother Daniel Bernoulli (1700–82) and James Hermann (1678–1733). Then in 1727 came Leonard Euler. He was then only twenty years of age, but he was destined to shed more lustre on mathematical science in Russia than any other individual. It is said that about half the memoirs in the *Transactions* of the Academy came from his pen. Joseph Delisle remained in Russia for twenty-one years establishing an observatory and lecturing to many students. His brother Louis Delisle de la Croyère served the State in various ways and perished with Behring on Behring Island in 1741. Nicolas Bernoulli died in St. Petersburg about a year after his arrival there, Daniel returned to Basle in 1733 while Hermann's stay was of the shortest. Three other men of science who were attracted to St. Petersburg in these early days were T. S. Bayer (1694–1738), who was given a chair of Greek and Roman antiquities, J. G. Gmelin (1709–55), professor of chemistry and natural history, and G. F. Muller (1705–83), who taught Latin, geography and history. The services of Muller led to his being called the "great father of Russian history".

One of the urgent needs of the Russian Government was a better knowledge of the many lands and races under its jurisdiction. Peter the Great had felt this need and for a number of years employed the German physician and naturalist Daniel Messerschmidt (1685–1735) to travel in Europe and Asia. On his journeys in Siberia Messerschmidt had the companionship of one of the many Swedish prisoners of war Peter had sent there. In the reign of the Empress Anne quite a large expedition was sent to explore Siberia from the Urals to the Pacific. Behring, the Danish

navigator, Delisle de la Croyère, Gmelin and Muller were among the leaders of this expedition which left St. Petersburg in 1733 and did not return until 1743. Others who afterwards took part in the expedition were the Russian botanist S. Krascheninnikof (1712–54), the German medical man and naturalist G. W. Steller (1709–45) and the German savant J. E. Fischer (1697–1771), who became professor of antiquities at St. Petersburg.

For ten years Gmelin, Muller and their fellows explored the plains and mountains of Siberia from Tobolsk to Okhotsk, sailed on the great rivers Ob, Yenisei and Lena, searched for the remains of the great animals from which fossil ivory had long been obtained, and gathered together a great mass of information on this vast and sparsely populated land. Behring and many of his companions died in 1741 in the Far East, and Steller after being wrecked and suffering years of hardship regained touch with the home authorities only to disappear for ever. Great results were achieved by the expedition and it paved the way for that of Pallas referred to in NATURE of September 20, p. 334.

In the years which separated these two expeditions considerable strides were made in the furtherance of science in the capital. The reign of Catherine had been followed by those of Anne and Elizabeth, and in 1762 the great Catherine II ascended the throne. The University of St. Petersburg was founded in 1747 ; that of Moscow in 1755. Perhaps the most notable figure in St. Petersburg at this time was Michael Lomonosof (1711–65), father of modern Russian literature. Educated partly at the Academy, he had studied chemistry, mineralogy and metallurgy in Germany. In 1745, G. W. Richmann was made professor of experimental philosophy ; in 1747, Muller was made historiographer to the Russian Empire, and in 1751, A. N. Grischow (1726–60) became professor of astronomy and secretary to the Academy. In 1753, the year Franklin received the Copley Medal of the Royal Society, Richmann was killed by lightning when repeating some of Franklin's experiments. In 1757 the scientific coterie was joined by Æpinus, who two years later at St. Petersburg published his "Tentamen Theoriæ Electricitatis et Magnetismi", one of the great works on electricity in the eighteenth century. In 1760 Rumoffski published his "Course of Mathematics", said to be the first printed in the Russian language. Rumoffski had studied under Euler in Berlin and he was well known as a mathematician, astronomer, geographer, traveller and teacher. When more than seventy years of age he was curator of the University of Kazan.

With the accession of Catherine II in 1762 a new era in Russian education, science and literature began. Of German parentage, even her marriage to a boorish prince and her long acquaintance with the intrigues and boredom of the Russian Court could not destroy her love of books. She was fond, too, of patronizing learned men. She was able, in 1766, to prevail upon Euler to return to St. Petersburg from Berlin ; she entertained Diderot like a prince ; she asked D'Alembert to become the royal tutor and she sent her portrait to the Irish chemist and mineralogist Kirwan. Soon after Euler returned to St. Petersburg, he was joined by the Swedish astronomer, Lexell, and by Nicolas Fuss (1755–1825). These proved great friends to Euler in his blindness. In 1776 the Academy of Sciences celebrated its jubilee and in Weld's "History" will be found the letter of Euler's son, J. A. Euler, announcing that the Academy had elected the president of the Royal Society, Sir John Pringle, a foreign associate. Euler's death in 1783 left a blank in the Russian mathematical world never filled. He had thirteen children and of these Jean Albert (1734–1800), was the professor of natural philosophy, Charles (d. 1790), was a doctor at the Russian court and Christopher (d. 1814) rose to be a major-general in the Russian Army. His son-in-law Nicolas Fuss, in 1800, became secretary of the Academy of Sciences, in which post he was succeeded by his son Paul Henry. Another son, George Albert Fuss, was one of the first assistants at Pulkowa Observatory.

Towards the end of the reign of Catherine (who died in 1796), and during the reigns of Paul and Alexander I, scientific work seems to have languished somewhat. No doubt this was partly due to the disturbed state of Europe during the French Revolution and the Napoleonic regime. After this period of comparative stagnation science took on fresh activities during the whole thirty years reign of Nicolas I, who ascended the throne in 1825. Though a monarch who declared that "Despotism is the essence of my government, and it suits the genius of the land", yet he was not averse to giving his blessing to scientific projects and showering gifts on men of science. On one occasion he sent a diamond ring to James Nasmyth, the engineer ; on another he presented a fine china vase to Snow Harris, the electrician, and when Airy, the Astronomer Royal, was refused permission by the British Foreign Office to accept a Russian knighthood, Nicolas had a gold medal especially struck for him.

Soon after Nicolas came to the throne the Academy of Sciences put forward a plan for a new central observatory. Nicolas, through his minister, replied in 1830 "that the honour of the country appeared to him to demand the establishment, near the capital, of a new astronomical observatory,

conformable to the actual state of Science, and capable of contributing to its ulterior advancement". In 1835 the foundation stone of the great Pulkowa Observatory was laid and in 1839 the institution was completed at a cost of about £100,000. It stands about ten miles south-east of Leningrad and unfortunately is now in the defensive zone of that city. Directed from 1839 until 1890, with but a brief break, by the Struves, father and son, it became a Mecca for astronomers, and Gould, the American astronomer, once called it "the astronomical capital of the world". The Struves had many able assistants and they were visited by eminent astronomers from all over the world. Russia was also greatly indebted to the Struves for their geodetical work which included the measurement of an arc of the meridian from the north of Scandinavia to the River Danube. When Otto Struve retired he was succeeded by Theodor Bredikhine (1831–1904) who previously had been professor of astronomy at Moscow, and he in turn was succeeded by Johan Backlund (1846–1916), who though Swedish by birth became a naturalized Russian.

The Government of Nicolas also did much to further magnetic and tidal observations and geographical and geological excursions. In 1828, Hansteen, the Norwegian physicist, accompanied by the German physicist, G. A. Erman, travelled to Siberia making magnetic observations, and their journey was followed by that of the great Humboldt who was accompanied by Ehrenberg and Gustav Rose, the chemist and mineralogist. It was Humboldt who put forward the plan for a world magnetic survey in which Great Britain and Russia took the leading part. Another expedition of note was that made in 1841–45 by Murchison, the French geologist de Verneuil and the Russian mineralogist N. I. Koksharov (1818–93), who, in 1865, became director of the Imperial Mineralogical Society of St. Petersburg. Two other eminent Russian geologists of this time were Gregor von Helmersen (1803–85), who, in 1841, published a geological map of Russia, and K. E. von Eichwald (1795–1876), professor of palæontology at St. Petersburg. The greatest naturalist of the reign of Nicolas in Russia, however, was the German, Karl E. von Baer (1792–1876), to whom the Royal Society in 1867 awarded the Copley Medal; this being the first time the medal had gone to Russia. Since von Baer's time it has been awarded to Metchnikoff, Mendeléeff and Pavlov.

It may be presumed that during the eighteenth century German and Swedish works on chemistry, mining and metallurgy found their way into the mining districts of European Russia and Siberia, but chemistry does not appear to have occupied an important place in the schools and universities. A Russian chemist whose name is mentioned in histories of chemistry is Klaus, the discoverer of ruthenium. Klaus was a professor at the University of Kazan founded in 1804. Among his students and contemporaries were Nicholas Zinin (1812–80) and Alexander Butlerow (1828–86). Both these men occupied chairs first at Kazan and then St. Petersburg. Another student and professor at Kazan was Wladimir Markownikoff (1838–1904), who in 1873 was given the chair of chemistry in the University of Moscow. Other leaders in Russian chemistry at this time were Friedrich Beilstein (1838–1906), Nicolas Menschutkin (1842–1907) and the great Mendeléeff, who was born at Tobolsk in 1834, being the youngest of the fourteen children of the director of the Tobolsk College. Mendeléeff's grandfather had produced the first Siberian newspaper.

Appreciations of these distinguished chemists are to be found either in the columns of NATURE or the *Journal of the Chemical Society*. Several of them made important investigations concerning the petroleum of the Caucasus, but it is worth recalling that it was the Swedish engineer Ludwig Nobel (1831–88), elder brother of Alfred Nobel, who revolutionized the Baku oil industry and introduced pipe lines, tank cars and tank steamers, making a fortune where others had failed.

The most famous scientific man connected with the University of Kazan was Nicolai Lobatschewski (1793–1856). "What Vesalius was to Galen, what Copernicus was to Ptolemy, that was Lobatschewski to Euclid", wrote Clifford. Kazan owed much to his organizing powers, and forty years after his death his bust was placed in the University and a prize founded in his honour. In human interest even Lobatschewski is surpassed by the remarkable woman mathematician, Sophie Kowalevski (1850–91). Her romantic marriage to Woldemar Kowalevski (1843–83), professor of palæontology at Moscow; his tragic death and her subsequent rise to fame make a story as interesting as one of her own novels. Her reputation was such that in 1886, when she was holding the chair of higher mathematics at Stockholm, the Paris Academy of Sciences broke through all the traditions of two centuries by admitting her to one of its meetings. As she entered, the whole of the members rose to salute her and the president declared that her presence should be a cause of pleasure not only to the mathematicians present but also to the whole company.

If space permitted, something might be said about the rise of engineering in Russia. One of Smeaton's last atmospheric engines was fitted up at Kronstadt, and both Smeaton and Watt were invited to Russia in the days of Catherine II. The first engineering shops in St. Petersburg were

set up by British engineers, among whom were the Bairds, Handyside and the younger Matthew Murray. The early history of the engineering and other industries in Russia, however, is receiving the attention of Prof. P. P. Zabarinskij and other members of the Institute for the History of Science and Technics of the Academy of Sciences of the U.S.S.R., and already many interesting documents and facts have been brought to light and published.

PRESENT-DAY SCIENCE AND TECHNOLOGY IN THE U.S.S.R.

By PROF. J. D. BERNAL, F.R.S.

SCIENCE is a collective human enterprise. It belongs to no country or race. Yet at different periods it has owed its chief advance to the activities of men first in one part of the world and then in another. Modern science originated in Italy in the sixteenth century, spread to the Low Countries, and thence to England and France. It was in England that it first achieved effective organization in the Royal Society. The nineteenth century saw it established in every industrial country of the world, notably in Germany and the United States. In each of these countries a characteristic contribution was made both to the extent of new knowledge and to the new means of gaining it. In this century, the contribution that the new Union of Socialist Soviet Republics has made to science is as significant as any of the major contributions of other origins in the past.

Science, of course, was not a new thing in Russia. It can date its introduction as a living force to the many-sided genius of Lomonosof in the eighteenth century; and Russians can well be proud of the achievements of such men as Mendeléeff and Pavlov. But all these were relatively isolated workers. In no sense could the state of science in Russia before the Revolution be compared with that of Germany or Great Britain. The great change which the revolution brought about was to make conscious for the first time the necessary connexion between the ordered development of science and the life and work of the whole community. In this, of course, the new Government was inspired by the ideas of Marx and Engels, who had taken a lifelong interest in the progress and importance of science. Lenin had a wider and deeper knowledge of science than any statesman of his day, and even in the most difficult period of famine and civil war he laid the foundations of an entirely new development of science.

The conscious utilization of science, though to a certain extent implicit in State scientific institutions such as the Kaiser Wilhelm Gesellschaft in Germany and the Department of Scientific and Industrial Research in Great Britain, was foreign to the Western democracies; and this has made it difficult for many scientific workers to understand and appreciate the achievements of Soviet science. The task that was undertaken was not to push forward the bounds of knowledge by the work of a few isolated specialists, but to make scientific the whole productive and cultural activity of 160 million people, only a tiny minority of whom had any previous acquaintance with science or technology. The first twenty years of the Republic's life was occupied in a double task: the building up of scientific education, and the application of science to industrial, agricultural and medical needs. It was first necessary to create a body of competent scientific workers, starting from the handful that had sufficed for the needs of the Tzarist State. In 1919 there were only forty trained physicists in the whole of the Union. New schools, new universities, new scientific research institutes had to be founded and manned, and the necessary scientific instruments manufactured for them. Meanwhile, immediate problems of electrification, communications and agriculture had to be solved. This gigantic task could only have been achieved because it had behind it the enthusiastic interest and support of the whole people. It is characteristic of times of rapid progress and reconstruction that interest in knowledge should reach new heights. It was so at the dawn of the Greek City State, in the Italian Renaissance, in Civil War England; and it was certainly so not only for the Russians, but also for the submerged subject races of the old Empire—Mongols, Kazaks, Turkmen, Tartars, Georgians and Armenians.

In the creation of a new world it would be idle to look for the quietly pursued excellence and sound and acute scholarship that characterize an old-established and stable society. Science in the Soviet Union is not like science in Denmark or Switzerland. Nevertheless, the contribution to the advancement of knowledge made by the Soviet Union has been marked and important. In certain fields, especially in technology, Soviet discoveries

and applications have already made a deep impression abroad. In physics, for example, the work of the Leningrad School on the mechanics of crystal deformation was the starting-point of much of the recent great advance in the understanding of the strength of materials and of ways of improving them.

The Soviet Union has also led in the application of low-temperature techniques to industrial uses, particularly for oxygen, hydrogen and methane, where Prof. P. Kapitza's new processes are being energetically developed. Proposals for radical innovations, such as underground gasification of coal, eliminating at one stroke the whole of the laborious task of the miner, are characteristic of the Soviet approach. The widespread and strictly scientific survey of mineral resources has already led to discoveries of new mineral deposits exceeding all expectations.

In agriculture, the advantages of a common scientific basis and the removal of obstruction from tradition or vested interest have led to remarkable developments, notably in vernalization, the production of new hybrids such as perennial wheat, and the improvement of stock through artificial insemination. The development of public health services on a universal and rational basis has probably contributed more than anything else to immediate human welfare, and the new and universal use of stored blood for transfusion is largely due to Soviet initiative.

It is not in these achievements, however, that the ultimate value of the developments that have taken place in the Soviet Union is to be found. They are, so to speak, only an indication of what is to come when the principles of the organized development and utilization of science can be fully carried out, not only in the Soviet Union but also in the world at large. Nothing has aroused such interest, and at the same time such opposition, in scientific circles as the idea first adopted in the Soviet Union of the planning of science. The opposition is now largely silenced, because the conditions of war have made most scientific workers realize in their actual practice that planning is not only necessary, but is also quite compatible with individual initiative and enterprise. Curiously enough, the very consideration of a science planned in relation to social needs brings to light new problems, which in themselves act as a stimulus to radically new discoveries, by breaking up traditional associations of ideas which are the most effective bar to progress.

The actual system of planning which has been evolved in the U.S.S.R. in the past twenty years is much more comprehensive and more closely integrated with the life of the country than anything in Great Britain even in war-time. The general direction of research is in the hands of the Academy of Sciences, which has grown from being an honorific society into a body controlling directly the research of some thousands of workers mainly on fundamental problems. The Academy is closely linked with the universities, which have grown enormously in number and size while steadily improving the standard of their scientific teaching. All university students are selected for ability and are supported by the State, as are the new science bursaries in Great Britain. In return, they must accept four or five years of work allotted to them after graduation. This system ensures an ample supply of the best brains for scientific and technical work. Already in 1934 the proportion of young men and women going to the university was five per cent, as against two per cent in Great Britain. Allowing for the greater population and for the fact that a far larger proportion take science, the annual output of scientific workers must be about twenty times what it is in Britain.

The greater part of the short-term research is carried out in the institutes of the commissariats of industry, agriculture and health. Research and development are closely linked, and the scientific workers are close to the problems arising in the workshop and the field. The actual plan of research is not imposed from above, but evolved after much discussion by the scientific workers themselves. It does not, however, stand by itself but is closely linked to the State Planning Commission, and thus forms part of the general production and cultural plan of the Union. The major short- and long-term problems are set by the needs of the country as a whole. How they are to be solved most quickly and effectively is left for the scientific workers themselves to determine. That is the essential safeguard for seeing that fundamental work is not neglected. The result of this integrated effort goes much beyond its immediate practical application ; it is producing a society that is scientific through and through.

The difficulties which, particularly in the years preceding the War, surrounded the work of Soviet men of science have often led to doubts in the rest of the scientific world as to the ultimate efficacy of the system adopted. The bitter test of war is showing that in this field also the Soviets were building better than we knew. It is to be hoped that, fighting together in a common cause, scientific workers in Great Britain will come to understand, far better than from any description, the new spirit and method which characterize science in the U.S.S.R., and that, in turn, we may be able to provide some of the advantages of a long tradition of discovery and criticism. The new world for which we are all fighting and working will need every contribution that science can bring.

BIOLOGICAL SCIENCE IN THE U.S.S.R.

By Dr. Joseph Needham, F.R.S.

THIS contribution is intended to be complementary to Prof. J. D. Bernal's account of science and technology in the U.S.S.R. It is obviously impossible for one scientific worker to do justice to all the many sides of work in such a vast field as biology in the Russian world, but in this respect I am so far happy that in some of the departments with which I am familiar, such as experimental morphology, the Russians have won a position of generally acknowledged leadership.

It is certainly true that since the Revolution of 1917 science has enjoyed greater State support, both moral and financial, than in any other country. But it seems on the whole that, owing to the policy of concentration on heavy industry and all those branches of science which connect with it, biological science rather lagged behind physics and chemistry. I visited Russia in 1935 in connexion with that very successful organization, the International Physiological Congress, and although my impression in viewing Russian laboratories at that time was that the general standard of work was not up to the best standards in Western countries or in the United States, I formed the belief that its upgrade was faster, and that parity would before long be reached or passed.

In biochemistry this has proved to be the case. Two instances of fundamental biochemical discoveries recently made in Russia may be given: first the identity of adenylpyrophosphatase with myosin itself by Engelhardt and Ljubimova. This connected for the first time the energy-providing phosphorylation cycles with the contractile machinery, since myosin is the contracting protein. Secondly, the elucidation of the phenomenon of trans-amination by Braunstein and Kritzman, revealed the transfer of nitrogen in the living cell parallel with that of phosphorus and hydrogen, about which so much is known. An interesting sidelight on the freedom of choice of work in Russia is that the biochemists at the Military Medical Academy at Leningrad specialized on problems of chemical embryology—an exceptionally unwarlike subject—in which valuable contributions were produced by Galwialo, Vladimirov and their colleagues. Similarly, the well-known vitalist and founder of the mitogenetic ray hypothesis, Gurwitsch, has always retained his chair in Moscow, in spite of his differences from official views. Little is now heard of this subject in any country, but it is well to remember that the majority of the work which claimed to support the existence of the rays was done outside Russia, and that some of its first and most sharp critics were Russian, such as Moissejeva of Kiev.

In experimental morphology and embryology there were formerly two main schools, one American, dealing with the development of invertebrates, the other German, dealing with that of vertebrates. Since 1933, the workers in this field, which in view of its German origin bears the name *Entwicklungsmechanik*, have almost all gone into exile, and the mantle fell upon the newer Russian school. Among its leaders were Koltzov (who so long ago as 1912, with but the Fischer polypeptide chain theory to go upon, suggested that the chromosome might be considered a giant protein molecule with the genes as side-chains), Schmalhausen (author and encourager of important work on growth-rates), Balinsky, Filatov, Dragomirov, and others. Balinsky and Filatov have specialized on the induction of the nose and ear; they discovered the extraordinary powers which nasal placode and ear-vesicle have in inducing limb-buds on the flank of the amphibian neurula. Umanski discovered the induction power of cancer tissue, and explored the integrity required in tissue responding to neural induction. Wolffian regeneration of the lens of the eye has been intensively studied by Popov, Manuilova and their colleagues. In this literature it is interesting to note the appearance of names such as Sikharulidze and Murtasi from those Near and Central Asiatic races which hitherto have never had an opportunity of contributing to the advance of science.

One characteristic line of attack developed by the Russian experimental morphologists is the fusion together of several pieces of the same material, a technique possibly suggested by, and certainly in line with, the dialectical materialist idea of the transformation of quantity into quality. Thus Lopaschov, in important work, surveyed the results obtained in differentiation when from one to ten organization centres are isolated and grown together. Similarly, Polezaiev went far to settle the disputed question of whether limb-bud blastemas are undetermined or not by transplanting several of them at once, not only one (which is often resorbed), on to the new site. In this way it was found that development is always selfwise (*herkunftsgemäss*). The problem of the loss of regeneration competence has been much studied by this worker, with Schaxel, Liosner, Voronzova, and others, while the biochemical aspects of the

regeneration process, never before explored, have been investigated by the school of Okunev, Blacher, Orechovitch, Kozmina, Vladimirova and many more. The association of the action of various proteolytic enzymes with the differentiation processes proceeding in parallel has thus been studied. Another case of comparisons between chemical and histological data would be the study of insect metamorphosis, which has been successfully pursued by Demjanovsky, Zolotarev and others; or the respiratory studies in fish development by the school of Trifonova.

It seems specially worthy of remark that the far-reaching support of experimental morphology in the Soviet Union has occurred in a country where, according to a common opinion, only research of immediate practical applications would be expected to find support. The fact is that no one can tell what practical applications a science may have. The Russians have, as it happens, benefited greatly by their backing of this pure science, since increasing knowledge of eye-transplantations has permitted of the grafting of parts of the eyes of dead persons into living blind patients, leading to the restoration of their sight. This operation is associated with the name of Filatov.

On the borderline between physiological morphology and genetics a great deal of work has been done. There is space only to mention the work of the Iljins on coat colour, of Rappoport on the production of phenocopies by treatment of flies with salts of metals, and of Vassin, who recognized in a naturally occurring semi-lethal genetic abnormality the persistence of the embryonic gill-slits, in sheep.

In pure genetics also there has been a vast effort. Vavilov, one of Russia's greatest men of science, travelled over the whole world and made collections of plant material which have no equal. A great deal of work is still being produced by his school, which came into conflict, in a celebrated controversy, with that of Lysenko (who has been called the Burbank of the Soviet Union). Lysenko was originally a plant physiologist who discovered a method, known as vernalization, of producing a spring-sown cereal from a winter-sown one—owing to the Russian winter climate a most desirable thing. It is not yet certain whether this achievement will have world-wide application. Later, Lysenko and his school became extremely critical of the generally accepted principles of classical Mendelism, and they are now repeating many of the fundamental experiments on which Mendelian theory has been based. Only time will show whether their experiments on the inheritance of acquired characters will have the same results as all previous such experiments, or whether perhaps in the process some valuable information, hitherto overlooked, will accrue. Some geneticists believe that some of Lysenko's results may be explained by virus infections. In any event, this controversy is an outstanding instance of the benefit which would be derived could the scientific workers of the Soviet Union in the future come into much closer contact with those of other countries.

Where genetics touches animal husbandry enormous progress has been made in Russia. The Soviet improvers of stock have not been hampered by the difficulty which exists in other countries, namely, that the pedigree breeds are in private ownership while the mass of cattle are unimproved. Artificial insemination, introduced by Ivanov and others, is practised on a large scale, permitting the wide dissemination of useful qualities.

In the foregoing survey, little has been said about the Russian zoological and botanical systematists, but I understand from competent colleagues that they have been worthily keeping up the great traditions of the last century on the foundations laid by Pallas and von Baer. A word should be added, however, about the marine biological stations, of which there are several; at least one near Murmansk, another on the Crimean coast, and a third near Vladivostock. The first-named of these produced valuable work on comparative biochemistry by Kreps and Verjbinskaia, and on comparative physiology by Koschtojanz; the third aided Okunev's work on regeneration. There are, moreover, certain special stations of interest, such as that at Sukhum-Kale on the Caucasian coast, devoted to the experimental neurology of apes, perhaps the only one existing anywhere apart from the Physiology School at Yale University.

In conclusion, a word on the facilities available to Russian biologists. My impressions are that work in a Russian laboratory resembles closely enough work here in Great Britain or in the United States, with the exception that there are considerably more technicians available for the use of the research workers, enabling them to concentrate on what is their proper business, the planning, carrying out, and interpretation of experiments. The subject of pay and opportunities cannot be dealt with here, but reference may be made to a contribution by Dr. M. Ruhemann on this subject in NATURE[1].

There can be no doubt that the U.S.S.R. has a vast contribution to make to world science, a contribution with a special quality that cannot be spared. We must hope that, after this War, contact between the scientific workers of the democracies and those of the Soviet Union will be far more intimate than what has been possible in the past.

PROPAGATION OF RADIO WAVES ROUND THE EARTH

By T. L. ECKERSLEY, F.R.S.
MARCONI'S WIRELESS TELEGRAPH CO.

CONSIDERING the use to which the transmission of radio waves is put, it is remarkable how few have studied the problem. Engineers are interested in the terminal apparatus—the great transmitting and receiving stations; and physicists seem to be more interested in sending radio waves to themselves in the investigation of the ionosphere than in studying the transmission to others across wide open spaces. Both activities are essential to the creation of communication links, but a study of the application of the results obtained by physicists and engineers is also essential.

The mechanism of radio transmission is the same as that of light. Both comprise wave motions in the ether, but the wave-lengths used in radio, although covering a wide range, are very different from those of light.

Radio waves vary from a few centimetres to 20–30 kilometres, that is, sixteen or more octaves. Light waves are of the order of 10^{-7} cm., and there is only about one octave of visible light. The enormous range of radio waves makes the study of propagation difficult, but at the same time most interesting. Different wave-lengths have been treated piecemeal by different methods, but there should be, and is, one general method by which all problems can be treated.

The earth is practically a sphere, and for theoretical purposes it can be treated as a homogeneous sphere of uniform electrical conductivity. Irregularities do not matter much to the first approximation.

The propagation of radio waves round such a sphere can be treated mathematically. This was originally done by the great mathematicians such as Poincaré, and others. The mathematics are difficult. They were put on a firm and unimpeachable basis by G. N. Watson at the instigation of Van der Pol. Watson's investigation showed that for long waves the earth behaved as if it were a perfect conductor, and the results are only applicable, without further development, to perfect conductors. The whole theory has now been developed in two independent ways which agree and are applicable whatever the conductivity or inductivity may be.

The results of this mathematical investigation are now clear and definite enough. Waves of which the length is small compared with the radius of the earth are, as in light, practically confined to the region above the plane which is tangent to the earth at the transmitter.

The waves from the transmitter travel out in straight lines, and most, practically all, of the earth is in shadow. Nevertheless, some radio energy can penetrate by diffraction into the shadow region, and the longer the wave-length the more easily it does so.

However this may be, diffraction alone, or bending round the earth, is entirely inadequate to produce a signal at, say, the antipodes on any wave used in radio.

Diffraction is most effective when the wave-length is large, but even the longest waves that can be conveniently used in radio communication are so weak at the antipodes that they need increasing by a factor of the order of 10^{11} in order to overcome outside noise, even when the highest powers are used.

It is clear that in the normal radio range it is quite impossible to produce workable signals at the antipodes, or even at distances greater than about 3,000–4,000 kilometres, without the help of some agency which bends the rays round the world. This agency we now know is the ionosphere, which has been largely investigated by physicists in the last ten years. All the long-distance short-wave broadcasts, all the long-distance high-speed beam services, and all the linking up of 99 per cent of the world's telephones would not exist but for the ionosphere. The study of radio transmission round the earth therefore devolves itself into the study of the ionosphere and its effect on long-distance communication.

There are two aspects:

(1) The investigation of the constitution of the ionosphere.

(2) The exploitation of this knowledge in radio communication.

THE IONOSPHERE

This is a region from 60 to 300 kilometres above the earth, in which a small proportion of the molecules are ionized, so that there is an appreciable atmosphere of electrons capable of reflecting and modifying wireless transmissions.

It is only recently that a detailed and fairly accurate knowledge of it has been obtained, by Appleton in Great Britain and by experiments initiated by Breit and Tuve in the United States.

The method by which the ionosphere, which at 100 or more kilometres is entirely out of direct reach, can be investigated, is very simple in

essence. Radio impulses a fraction of a millisecond in length are sent up to the ionosphere, where they are reflected down to earth again. From the delay of the reflected echoes, their intensity and polarization, etc., a great many characteristics of the ionosphere can be deduced.

Measurements have been made at a large number of places on the surface of the earth, but the results are by no means sufficient. From these we know that there exists in all places examined a region between 60 and 300 km. above the earth in which there is an appreciable number of free electrons, reaching a concentration as great at 10^7–10^6 per c.c. This maximum density is an important characteristic of the layer. It is easily found with the impulse technique already described.

If the radio frequency of the exploring impulses is increased, their delay (that is, the time it takes for the impulses to travel up to the ionosphere and back) rapidly increases, and beyond a certain frequency the rays penetrate the upper layer and echoes cease. This critical frequency gives the maximum electronic concentration in the various layers of which the ionosphere is composed. Near the critical frequency, the curve which is known as the $P'f$ curve, relating delay time and radio frequency is split into two nearly circularly polarized branches, this being effected by the earth's magnetic field.

This critical frequency varies with the height of the layer concerned, the time of the day, season, epoch of the sunspot cycle, etc. It is possible, therefore, even with the limited observations at our disposal, to chart the world.

It is found, in effect, that wherever observations are taken, the curves relating delay and frequency are of the same general type, indicating the existence of three main layers, the E, F_1 and F_2 layers, approximately at heights of 100 km., 200 km. and 250–300 km.

A great deal has been found out about the ionosphere. Thus the E and F_1 layers behave normally and vary diurnally, seasonally and with the epoch in the sunspot cycle, as if ionized by the sun's ultra-violet radiation. The F_2 layer behaves in an anomalous manner. For example, contrary to expectation, the electron concentration in England is less in summer than in winter. Again, the concentration is different in the northern and southern hemispheres. There appears to be some annual ionizing agency independent of the sun.

By determining the polarization of the two branches of the $P'f$ curves near penetration in the northern and southern hemispheres, it has been found that the electron atmosphere is the major factor in guiding wireless waves. A positive ion atmosphere may exist in the lower E layer, but on account of the mass of the positive ions compared with the electrons, these have to be enormously in excess (10,000 to 1 or so) in order to affect the wireless waves. All we can say is that, experimentally, this excess does not exist.

One of the major factors in radio transmission is the attenuation of the waves. This is primarily caused by the collision of the electrons with the rest of the molecules. The electrons receive energy from the waves which is wasted as heat in collisions with the molecules.

By making experiments on the loss in reflexion as the impulses are delayed, it is possible to determine the collision frequencies at various heights, this quantity being of the order of 10^6 in the E layer and about 5×10^3 in the F layer.

The ionosphere is disturbed by the mechanism which produces magnetic storms, and also by bright hydrogen eruptions from the sun. This pathology of the ionosphere is of great consequence to communication engineers, and much has been learned about it.

PROPAGATION: GENERAL

With the help of this knowledge of the ionosphere, it is possible to get a very fair idea of the propagation of radio waves round the world, and to deduce, for example, which waves are least attenuated and can travel the greatest distances.

Short waves, 10–100 metres, which have been extensively used in world-wide communications, are easiest to understand because ray methods can be used; and, just as in optics, it is possible to trace the rays modified by refraction in the ionosphere. The analysis of these short waves is, in fact, a branch of optics; but when the wavelength becomes comparable with the radius of curvature of the rays, wave methods, and not optics, must be used. Attenuation also largely modifies optical methods, and for exactness and proper understanding, optical methods should be discarded and wave methods used everywhere. Nevertheless, it is sufficient to use optical methods on short-wave ranges.

The correct mathematical method, which should be applicable to the whole of the radio range, is to determine the solution of the equations of propagation in the ionosphere, in the region between the earth and the ionosphere, and in the earth itself, and to satisfy the boundary conditions at the surface of the earth and ionosphere respectively. The difficulty is in obtaining solutions of propagation in the ionosphere, which depend on fourth order differential equations when account is taken of the earth's field.

An approximate development of this is a phase integral method similar to that used in quantum mechanics, which, if the change of phase and

amplitude on reflexion at the ionosphere are known, is exactly equivalent to the above boundary problems. This phase integral often yields solutions in which methods are much simpler than in the boundary problems, and has been made to give a solution of the diffraction problem in which general relations of great interest are found. These methods—of universal significance—degenerate into optical ray methods for short waves (10–100 metres).

SHORT-WAVE TRANSMISSIONS

The application of our knowledge of the ionosphere is enormously helped by a proposition which translates the vertical $P'f$ results into relations for oblique transmission. Thus, if the critical frequency for vertical transmission is known, the critical frequency and consequently skip distance at oblique incidence are also known. This has been checked by an elaborate experiment between Chelmsford and Bodmin. With a sufficiently short wave, even the tangent ray escapes, so that even though it requires a much smaller electron concentration to bend the rays through a small angle, as in long-distance communication, there is ultimately a maximum usable frequency which is about four times the vertical critical frequency. Ground waves can, of course, be used at much higher frequencies. The above theorem is only exactly true if the earth's curvature and steady magnetic field are neglected.

The maximum usable frequency can be shown on a chart in which contours of the quantity are given. To the first approximation, the state of the ionosphere, and hence the contours of this chart, depend only on the sun's position. The chart can be drawn on transparent paper and slid over a map to give the maximum usable frequency for long-distance communication on any route. Complications in transmission may be produced by irregularities in the E layer, which are known to exist, but the cause of which is as yet unknown.

Short-wave transmission is very largely explainable on these optical lines. Each ray usually passes through the E layer up to the F layer, where it is reflected. In the passage through the E layer, it is attenuated by an amount proportional to the square of the wave-length. The shortest waves travel farthest provided they are not too short to be reflected.

LONGER WAVES

Experiment shows that above about 1,000 metres any increase in the wave-length increases the range, and extreme world-wide ranges can be obtained if waves of the order of 20–30 km. are used. These were originally employed in radio, until it was found that outside noise was so great on these frequencies, and the expense of the gear so high, that the use of such waves became uneconomic.

The behaviour of these waves can easily be explained, but not by ray methods. The boundary value or phase integral wave method must be used.

On these frequencies, 300 kc./sec. and less, there are no rays in the ionosphere, and we know that all the radio energy is confined to the E layer. The propagation in the E layer is not that of the propagation in a free electron atmosphere. Electron collisions with molecules are predominant, and the electrons do not move freely. The ionosphere behaves like a metallic conductor, and the parameter which controls the type of transmission is the ratio of the collision frequency ν_c to π times the actual frequency ν. When this quantity α is large, the ionosphere behaves like a conductor; when it is small, like an Eccles–Larmor refractive medium. In this, the rays reach a level where the concentration is proportional to the square of the frequency.

In a conductor, on the other hand, there are no rays at all, and the energy only reaches a level which varies inversely as the square root of the frequency.

The transmission may be considered to be guided between two shells, the E region of the ionosphere on the outside and the earth on the inside. The attenuation depends on the resistivity of the shells. This, on account of skin effect, or the diminishing penetration into the layer on these frequencies, increases with increasing frequency; that is, attenuation is proportional to $\sqrt{\nu}$, according to the 'Austin Cohen' law.

We therefore obtain the general fact that only extreme wave lengths, the longest and shortest, are useful for long-distance transmission, and this is the characteristic to which the correct treatment by boundary conditions or phase integrals leads. There is a maximum attenuation in day-time on the broadcast band (500–1,500 kc./sec.) and at such times the propagation is mostly, if not entirely, carried out by the ground ray, and is independent of the ionosphere. At night-time the layer changes; α decreases, and there are reflections from the ionosphere and consequent distortions.

The character of transmission depends on the collision frequency in the E layer, and day-time attenuations are a maximum and ranges a minimum on the broadcast band.

Only a general account of radio propagation has been given. Much remains to be done in explaining the vagaries of the ionosphere, but the general characteristics of long-distance radio communication are now well known.

OBITUARIES

Mr. C. M. Hutchinson, C.I.E.

MR. CLAUD MACKENZIE HUTCHINSON, who died on August 2, at the age of seventy-two, was a pioneer in the field of agricultural bacteriology in India and also contributed notably to a wide variety of problems of tropical soil, fermentation and medical science. He was educated at Glenalmond and St. John's, Cambridge, where he got his 'blue' for golf in 1889–90 and graduated in 1891.

After some years as professor of chemistry at the Colonial College, Hollesley, he joined the scientific staff of the Indian Tea Association in Assam in 1904 and succeeded Dr. Harold H. Mann as scientific officer to the Association in 1907. In 1909 he was appointed Imperial agricultural bacteriologist at Pusa. He retired from the Indian Agricultural Service in 1926 and soon afterwards became chief scientific adviser to Messrs. Imperial Chemical Industries (India), a post he held until he returned to Great Britain in 1931.

Hutchinson's best scientific work was done at Pusa and received official recognition by the C.I.E. conferred on him in 1920. While in Assam he became interested in the cycle of nitrogen in tropical soils and this subject occupied much of his time and thought at Pusa. His publications on the influence of bacteria on soil fertility (1911), on nitrogen fixation in Indian soils (1919), on nitrogenous fertilizers in India (1919), on fermented green manures (1923) and on the conservation of humus in Indian soils (1927) were offshoots from this work but the main part was never published, for a serious illness struck him down a few days after he started to assemble the results on his return from the East. But the work itself had a widely stimulating effect in India: to cite one instance only, it was Hutchinson's studies on the fermenting of green plant residues that led to R. D. Anstead's activated composts, afterwards developed in conjunction with Gilbert Fowler and now attracting so much attention in Great Britain in connexion with the disposal of town waste.

An outstanding work on the bacterial wilt of tobacco, a fascinating study of the rice beer ferment 'bakr', work on the pebrine disease of silkworms, on the bacteriology of indigo manufacture and on indigenous sources of phosphoric acid, the development with W. Hodgkinson of the electrolytic chlorine (E.C.) process of sterilizing water, studies on the micro-anatomy of Cimex for the research workers on kala azar, and on antiseptic measures for use in sugar factories, were some of the other scientific contributions from an astonishingly fertile mind.

This versatility was the keynote of Hutchinson's character. He was an exceptionally gifted photographer and in addition to making the photographic section at Pusa one of the best of its kind, published notes on photographic illustrations and on photomicrography, and prepared a number of cinema films for agricultural propaganda. His advice on the laying down and maintenance of turf for golf courses was much sought. Landscape painting and bridge, at which he was highly proficient, were a solace when illness prevented outdoor activities, as was increasingly the case in recent years. He was an interesting and refreshingly acid conversationalist and debater.

Many friends will mourn a picturesque and stimulating personality. His marriage in 1914 to Alice Muriel, daughter of J. Walter Leather, Imperial agricultural chemist at Pusa, who survives him, was an exceptionally happy one; her untiring care did much to make possible the considerable scientific output he accomplished in spite of persistent illness.

E. J. BUTLER.

Dr. H. R. Spencer

DR. HERBERT RITCHIE SPENCER, the well-known London consultant in obstetrics and gynæcology, who died on August 28, was born at Atherstone in Warwickshire on January 16, 1860. Contrary to what has sometimes been stated, he was no relation of his namesake the famous philosopher. He received his scientific and medical education at University College, London.

Besides numerous contributions to periodical literature on the clinical aspects of his speciality he took a keen interest in its historical side and medical history generally. He played an active part in the Third International Congress of the History of Medicine held in London in 1922, and delivered the Harveian Oration before the Royal College of Physicians on "William Harvey: Obs etric Physician and Gynæcologist" in 1921, the Fitzpatrick Lecture before the same body on "The History of British Midwifery (1650–1800)" in 1927, and the Lloyd Roberts Lecture on "The Renaissance of Midwifery" before the Medical Society of London in 1924. He also read a paper at University College Hospital on "Medicine in the Days of Shakespeare" in 1929. He possessed a remarkable collection of old books connected with his subject, besides being a constant reader in the library of the Royal Society of Medicine and a valuable member of the Library Committees of this Society and of the Royal College of Physicians for many years. He was an accomplished scholar and delighted in translating Horace and Goethe.

Spencer received many distinctions at home and abroad. He was honorary LL.D. of the University of Aberdeen, and in 1923 was president of the Medical Society of London.

J. D. ROLLESTON.

WE regret to announce the following deaths:

Mr. W. H. Caldwell, formerly University lecturer in biology in the University of Cambridge, known for his work on the embryology of the Monotremata and Marsupialia, on August 28, aged eighty-two.

Mr. H. Grindell-Matthews, known for his inventions in the field of radio-telephony, on September 11, aged sixty-one.

Dr. Robert Thomas Hill, geologist of the United States Geological Survey during 1889–1904, aged eighty-three.

NEWS AND VIEWS

Sunspot and Magnetic Storm of September 18–20

THE largest group of sunspots since January 1940 crossed the sun's disk between September 10 and 23. The group was a complex stream of spots some 150,000 miles in length, and its maximum area exceeded 2,000 millionths of the sun's hemisphere, or about 2,300 millions of square miles. At central meridian passage on September 16·8, the centre of the group passed within 4° of the centre of the sun's disk. Thus the earth was in a favourable position to be affected by a corpuscular stream that might be shot out from this disturbed region within a day or two of September 16·8. Statistical data of sunspots and magnetic storms show that out of every ten spot-groups of great size (1,500 millionths of the sun's hemisphere or greater), seven groups are associated near the time of their central meridan passage with a magnetic storm, the mean position of the group at the time of the commencement of the storm being about one day past the central meridian (see the *Observatory*, 62, 319; 1939). A valuable criterion of especially active spot groups is the occurrence of brilliant chromospheric eruptions, or 'solar flares' (*loc. cit.*, p. 321), which may be observed in monochromatic light at certain wavelengths only—the solar spectrum lines generally used being C for visual observations and H and K for photographic records.

In the present case, a brilliant eruption was observed at Greenwich on September 17 at 8½h. U.T., this being associated with an ionospheric irruption (fade-out). About 20 hours later, a magnetic disturbance began; this developed into a great storm which proclaimed itself by disturbance on radio circuits and by displays of the aurora borealis. As recorded at Abinger, a first climax of disturbance was shown by the magnetic traces between 7h. 2m. and 7h. 6m. on September 18, but the maximum of the storm as a whole was reached at about 0h. on September 19. The total ranges recorded throughout were: 120′ in declination, 1,250 γ in horizontal force and more than 1,100 γ in vertical force. This storm is one of the most intense of the present solar cycle, other notable storms being those of January 25–26, 1938, April 16, 1938, March 24–25, 1940, and March 1, 1941. The maximum of sunspot frequency occurred in 1937–38.

Hermann Nothnagel (1841–1905)

PROF. HERMANN NOTHNAGEL, one of the most eminent research workers and clinicians in the second half of the nineteenth century, was born at Alt-Lietzgöriche in Brandenburg on September 28, 1941, the son of a medical man. After holding the chair of pharmacology at Freiburg in 1872 and that of special pathology and therapeutics at Jena in 1874, he was appointed professor of medicine at Vienna in 1883, and held this post until his death. Besides numerous valuable publications on neurology and pharmacology, many of which were translated into English, French, Italian, Portuguese and Polish, he edited a system of special pathology and treatment in twenty-four volumes (1894–1905), to which he contributed a classical monograph on diseases of the intestine and periton um. In conjunction with von Leyden he founded the *Zeitschrift für Klinische Medizin* in 1880, and was the founder and first president of the Vienna Society for Internal Medicine. He died on July 7, 1905.

Grass as Human Food

IN NATURE of July 19, p. 90, this problem was discussed briefly with special reference to an interesting pamphlet "Eating for Victory" by Mr. J. R. B. Branson, and it was pointed out that the main objection to the inclusion of grass in the human diet lies in its high content of cellulose. Mr. Branson has suggested to us that the danger from this source has been unduly emphasized. He recalls that in a paper read before the British Association in 1937, Dr. R. E. Slade stated that the dry matter in the leaf of the grass plant consists largely of soluble carbohydrates and proteins, together with minerals and vitamins, and that it is not until the plant begins to ripen that the carbohydrates change to cellulose and the protein moves from the leaf into the flower and seed. Moreover, according to data provided by Dr. H. E. Woodman, the dry matter of newly grown grass-leaf such as one gets in lawn-mowings, contains as much as 26·5 per cent of protein, 44·5 per cent of carbohydrate and 5·5 per cent of oil, making a total of 76·5 per cent of digestible matter.

The presence of valuable nutrients in young grass will not be denied, but the cellulose content of the remaining 23·5 per cent makes it questionable how much young grass, if indeed any, can be safely eaten over prolonged periods by the average human subject. The physical state of the cellulose, which is in long fibres liable to become bound into large obstructive masses, must be borne in mind. It would seem dangerous, therefore, to advocate the use of grass as an ordinary article of diet without the evidence of extensive scientific experiments as to the amount which can be safely ingested without overloading the excretory powers of the intestines.

Sound Integrating Machine

EXPLORING the sound field around a small source such as a bell or loud-speaker is usually a laborious and time-consuming task because it involves making many measurements in all directions around the radiating source. In the *Bell Laboratories Record* of July it is shown how this effort can be avoided by doing the work automatically with a sound-integrating machine. The apparatus to be tested is rotated on a turn-table while a small condenser microphone, which is mounted on the end of an arm, is swept backwards and forwards over it. This arm is oscillated in a vertical plane through an angle of 180° by a cam which moves it progressively more slowly as it approaches the ends of its excursion, so that equal

radiating areas are traversed in equal times. The output of the microphone is amplified and applied to an analyser to determine the sound intensity in different frequency bands. A meter reading gives the average intensity of the sound in a selected band : and multiplication by a factor, involving the area of a hemisphere the radius of which is the length of microphone arm, gives the total power radiated in that particular band. This integrator measures sound outputs in about one fiftieth of the time previously required to make separate observations at many points about the source. It has been used extensively in developing telephone set housings.

Electrical Demonstration Equipment

IN the *Bell Laboratories Record* of July a description is given by C. D. Hanscom of a variety of equipment which has recently been assembled by the Bell System for use in public lectures. One of the most unusual demonstrations is a Rochelle salt crystal which flashes a neon lamp when hit with a gavel. This illustrates how a change in mechanical dimensions caused by the blow generates momentary voltages of considerable magnitude by the piezoelectric effect. A bar of steel (a permanent magnet) floating in mid-air demonstrates the power of modern magnets. A permanent magnet concealed in the base of the apparatus repels the bar, holding it up against the force of gravity ; a full packet of cigarettes can be supported in addition to the bar. There are also in the collection permalloy rods which are so permeable that they are magnetized by the earth's field, when held pointing north at or near the angle of declination. This is demonstrated by their ability to attract and hold short pieces of permalloy tape.

Decreased size of loading coils, made possible by research on magnetic alloys, is illustrated by a display board on which are mounted a coil with an iron-dust core, a much smaller coil of equal efficiency with a permalloy core, and a still smaller one with the same electrical characteristic, the core of which is molybdenum permalloy. Samples of the 2121-pair cable for exchange areas are included ; also a piece of the Minneapolis-Stevens Point coaxial cable which transmits frequencies of several million vibrations per second. A replica of Bell's original telephone is usually included with the exhibits.

Photography in Stellar Astronomy

A RADIO talk by the late Dr. Annie J. Cannon, entitled "The Story of Starlight", delivered on January 18 last, from Harvard Observatory, appears in the *Telescope* of May–June. A short description is given of the developments in spectroscopy since 1666 when Newton bought a crude prism at a country fair, "to try therewith the phenomena of colour". It is remarkable that two hundred years elapsed before Newton's work was carried to fruition, but when the potentialities in the study of spectra were realized, there was joy in being an astronomer. As Sir William Huggins remarked, "Those were the days when there was something worth while to do in astronomy". Dr. Cannon gives a brief account of photographic developments with special reference to the work of Harvard, where there are half a million negatives, which may be likened to a library of first and only editions, the whole forming the sole record of events observed in the stellar universe during the last half-century. The brief survey includes the important discovery of Miss Leavitt on the relation between the period of pulsation of a Cepheid variable star and its candle-power—a discovery which provides the data for determining the distances of these stars. This radio talk will be read with interest by the amateur astronomer.

Nature Study for Evacuees

THE Universities' Federation for Animal Welfare (U.F.A.W.) has issued two further useful and informative lectures for delivery to evacuee children, namely "British Snakes and Lizards", by Dr. R. C. Blackie, curator of Exeter Museum, and "Frogs and Toads", by E. M. Stevenson, lecturer in biology, University College, Exeter. The lectures are printed as brochures and accompanied by photographic plates for illustration and will help to solve a very pressing problem with many town teachers inexperienced of the countryside where they are now evacuated with their inquiring pupils. In a similar way, the various branches of the Workers' Educational Association have included nature study, biology, botany and kindred subjects in their programme of lecture courses for the coming winter. The West Lancashire and Cheshire Branch of the W.E.A., for example, is arranging nature study courses this winter at the University of Liverpool, Neston Library, Runcorn Technical Institute, Southport Technical Institute and probably Maghull Library, with a special appeal to teachers, and biology classes at the University and some of the branch towns. Attention has been given to nature study at the large Colomendey school camp, North Wales, but in most parts of the country considerable help in this subject is still required by town teachers in care of evacuees but handicapped by the limitations of their own experience of field natural history, which differs so radically from laboratory biology. A "Junior Naturalists' Society" has been formed by F. Stodart at Longfield, Kent, and much help is being given by local branches of the British Empire Naturalists' Association.

Bug Infestation

IN his latest annual report Sir Alexander Macgregor, medical officer of health for Glasgow, states that the total number of houses in that city in which bed bugs were found in 1939 was 309, or 2·1 per cent, as compared with 3·1 per cent in 1938. In 79 houses, or 0·5 per cent only, a "trace" of bed bugs was found, as compared with 0·9 per cent in 1938. In this group only old hatched eggs were found, but no living bugs or eggs were detected in beds or furniture, pictures or household belongings. In 62 houses, or 0·4 per cent compared with 0·5 per cent in 1938, a medium degree of infestation was found, that is, living bugs or eggs were present, but not in the

structure of the house itself. In 168 houses, or 1·2 per cent, a serious degree of infestation was found, living bugs or eggs being present not only in the beds or on furniture but also in the structure of the rooms such as picture rail, skirting and door facings. In the great majority of houses infestation was detected at a fairly early stage by the nurse inspectors. The progress made in the prevention of any infestation during the last six years is shown by a fall from 10·7 per cent in 1934 to 2·1 per cent in 1939 and by a fall of serious infestation from 7·1 to 1·2 per cent during the same period.

Public Health in Mexico

ACCORDING to the *British Medical Journal* of August 9, the National University of Mexico, four years ago, founded its social service system under which every medical graduate is required to practise for five months as a health officer in some part of the country where there is no such representative. He sends in a weekly report of contagious diseases cases seen, and a monthly report which includes information on sanitary questions such as water supply and drainage. Since 1935 more than a hundred graduates have taken part in this social service programme.

Recent Earthquakes

THE provisional epicentres of two earthquakes have recently been found by the United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association. The first, on June 18, 1941, had its epicentre near lat. 51·5° N., long. 32° W., which is in the North Atlantic Ocean on the ridge which stretches from Greenland to the Azores. Occasional earthquakes are known to occur from time to time on this ridge, showing that it is still one of the unstable regions of the earth. The second shock, on June 26, had its epicentre near lat. 13° N., long. 93° E., which is near the Andaman Islands in the Bay of Bengal.

Sixteen large distant earthquakes were registered on the seismograms at Kew Observatory during August 1941. The greatest was on August 2, when a ground amplitude of 91 μ was attained at Kew, and a full suite of pulses was obtained on August 4, 6, 9, 15 (see NATURE, Sept. 13), 19, and 30. The shock on August 6 at an estimated epicentral distance of 8,800 km. had a probable depth of focus of 200 km. On August 9 there were six shocks, five being from an estimated epicentral distance of 2,030 km.

The Night Sky in October

THE moon is full on Oct. 5d. 8h. 32m. and new on Oct. 27d. 20h. 9m. There will be an occultation of the first magnitude star α Tauri on October 10, the disappearance as seen from Greenwich taking place at 3h. 16·1m. and the reappearance at 4h. 30·1m., the position angles being 290° and 252° respectively. Lunar conjunctions with the planets will be as follows: Mars on Oct. 5d. 23h., Mars 1° S.; Saturn on Oct. 9d. 4h., Saturn 2° N.; Jupiter on Oct. 11d. 4h., Jupiter 5° N.; Venus on Oct. 23d. 17h., Venus 8° S. Mercury is an evening star until Oct. 26 and then becomes a morning star. Venus is an evening star and sets at 18h. 38m. at the beginning and at 18h. 19m. at the end of the month. Mars is a morning star until Oct. 10 when it is in opposition to the sun, and then it is an evening star. At the beginning and end of the month the planet souths at 0h. 41m. and 22h. 6m. respectively. Jupiter is a morning star and crosses the meridian at 4h. 44m. on Oct. 1 and at 2h. 44m. on Oct. 31. Saturn is a morning star, the meridian passages being at 3h. 8m. and 1h. 7.m at the beginning and end of the month respectively. The Orionid meteor shower will commence about Oct. 18 and will continue for a few nights; the radiant point is close to ν Orionis. Comet van Gent (1941d) will be visible with the aid of a small telescope during the month. It will be easily identified, a 3-inch refractor showing it quite distinctly, as its magnitude is about 8·5. The comet is moving northward in declination in the constellation Ursa Major, and on Oct. 19 will be close to ψ Ursæ Majoris. Its distances from the earth and sun in the middle of the month will be nearly the same—about 108 million miles. Although it is receding from the Sun it is still approaching the Earth, for which reason its magnitude will not vary very much during the month, that due to the increase in distance from the Sun being nearly balanced by the change due to the decrease in distance from the Earth. An ephemeris for every four nights is given for the comet. A short ephemeris was given in NATURE of Aug. 2, p. 139.

EPHEMERIS FOR COMET VAN GENT (1941*d*).

Announcements

DR. W. H. MILLS, F.R.S., emeritus reader in stereochemistry in the University of Cambridge, has been elected president of the Chemical Society until the next annual general meeting.

A meeting to celebrate the tercentenary of the arrival of Comenius in London will be held at the Caxton Hall, London, on September 29. The Archbishop of York will preside, and the principal speakers will be the Prime Minister of the Netherlands and the Foreign Minister of Czechoslovakia. A further meeting will be held at Cambridge on October 24 (see NATURE, Aug. 23, p. 222).

ERRATUM. In the letter entitled "Specific Heat of Supra-Conductive Tantalum" by Dr. K. Mendelssohn in NATURE of September 13, p. 316, the graph as printed is inverted. It should be read as if turned through 180°, without shifting the numerals of the ordinates.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Radiations from Bromine (82)

AN account has recently appeared of some work by J. R. Downing and A. Roberts[1] on the radiations from radioactive bromine, ^{82}Br, of period 34 hours. As their results differ in some important particulars from those I have obtained in a similar series of experiments it seems desirable to mention my results briefly. It was intended to carry out the investigations in some detail, but the work had to be abandoned in the spring of 1940 for more urgent duties, and it seems unlikely that I shall be able to resume it for some time.

The radioactive bromine was prepared by irradiating a thin selenium layer evaporated on gold foil with a beam of 4 Mev. protons from the cyclotron. After the decay of the short-period elements the radiations emitted from ^{82}Br were investigated by means of Geiger-Müller counters in the following methods: absorption of β-rays, absorption of γ-rays, absorption of Compton-electrons produced by γ-rays, β-γ and γ-γ coincidences. The results obtained were as follows.
